DEDICATION

When it comes to the future, there are three kinds of people: those who let it happen, those who make it happen, and those who wonder what happened.

—John M. Richardson, Jr.

This book is dedicated to our students, past, present, and future, who we know are well equipped to make it happen.

TABLE OF CONTENTS

CONTRIBUTORS

REVIEWERS

SECTION I—MAGNITUDE/SIGNIFICANCE OF DRUG-INDUCED DISEASES: IMPACT ON THE HEALTHCARE SYSTEM

Chapter 1: Drug Safety and Drug-Induced Diseases: The Regulatory, Legal, and Practice Environments
Cynthia Reilly, MS, BS Pharm

Chapter 2: Epidemiology and Public Health Impact of Drug-Induced Diseases
John R. Litaker, PhD, MSc, MMedSc, and James P. Wilson, PharmD, PhD, FASHP

Chapter 3: Factors Contributing to Drug-Induced Diseases
Tyler Shugg, PharmD, Abdullah Assiri, PharmD, and Brian R. Overholser, PharmD

Chapter 4: Postmarketing Surveillance for Drug-Induced Diseases
Tobias Peschel, MD, PhD, MBA, and Hugh H. Tilson, MD, DrPH

Chapter 5: Evaluating Patients for Drug-Induced Diseases
Douglas A. Miller, PharmD, and James E. Tisdale, PharmD, BCPS, FCCP, FAPhA, FNAP, FAHA

SECTION II—DRUG-INDUCED DERMATOLOGIC DISEASES

Chapter 6: Drug Allergy and Cutaneous Diseases
Lynne M. Sylvia, PharmD

Chapter 7: Systemic Lupus Erythematosus-Like Syndrome
Karen W. Lee, PharmD, BCPS, and Matthew F. Ambury, PharmD, BCPS

Chapter 8: Photosensitivity
Julie M. Koehler, PharmD, FCCP

Chapter 9: Alopecia, Hirsutism, and Hypertrichosis
Kristine E. Keplar, PharmD

SECTION III—DRUG-INDUCED NEUROLOGICAL DISEASES

Chapter 10: Seizures
Timothy E. Welty, PharmD, FCCP, BCPS

Chapter 11: Stroke
Denise H. Rhoney, PharmD, FCCP, FCCM, FNCS

Chapter 12: Movement Disorders
Jack J. Chen, PharmD, FASCP, FCCP, BCPS, BCGP; Khashayar Dashtipour, MD, PhD; and David M. Swope, MD

Chapter 13: Peripheral Neuropathy
Dennis Parker, Jr., PharmD

Chapter 14: Visual Disturbances
Yaman Kaakeh, PharmD, BCPS, BCNSP, CNSC, and Steven R. Abel, PharmD, FASHP

Chapter 15: Delirium
Matthew A. Fuller, PharmD, FASHP, BCPP

Chapter 16: Sleep Disorders
Lisa L. Forsyth, PharmD, FCCM

Chapter 17: Cognitive Disorders
Michele Y. Splinter, PharmD, MS, BCPS, FCCP

SECTION IV—DRUG-INDUCED PSYCHIATRIC DISEASES

Chapter 18: Depression
Sheila Botts, PharmD, FCCP, BCPP, and Melody Ryan, PharmD, MPH

Chapter 19: Anxiety
Julie A. Dopheide, PharmD, BCPP, FASHP, and Seth Gomez, PharmD, BCPP

Chapter 20: Psychosis
Jessica L. Gören, PharmD, BCPP

SECTION V—DRUG-INDUCED PULMONARY DISEASES

Chapter 21: Interstitial Lung Disease/Pulmonary Fibrosis
Jordan R. Covvey, PharmD, PhD, BCPS, and Erin E. Mancl, PharmD, BCPS, BCCCP

Chapter 22: Asthma and Bronchospasm
Suzanne G. Bollmeier, PharmD, BCPS, AE-C, and Rebecca L. Stauffer, PharmD, BCPS

SECTION VI—DRUG-INDUCED CARDIOVASCULAR DISEASES

Chapter 23: Myocardial Ischemia and Acute Coronary Syndromes
Kevin M. Sowinski, PharmD, FCCP

Chapter 24: Heart Failure
Yazid N. Al Hamarneh BSc(Pharm), PhD, and Ross T. Tsuyuki, BSc(Pharm), PharmD, MSc, FCSHP, FACC, FCAHS

Chapter 25: Ventricular Arrhythmias
James E. Tisdale, PharmD, BCPS, FCCP, FAPhA, FNAP, FAHA

Chapter 26: Supraventricular Arrhythmias
James E. Tisdale, PharmD, BCPS, FCCP, FAPhA, FNAP, FAHA

Chapter 27: Hypertension
Liza W. Claus, PharmD, BCACP, and Joseph J. Saseen, PharmD, BCPS, BCACP, FCCP, FASHP

Chapter 28: Hypotension
Katy E. Trinkley, PharmD, BCACP, and Robert L. Page II, PharmD, MSPH, BCPS (AQ-Cardiology), BCGP, FCCP, FAHA, FASHP, FHFSA

Chapter 29: Valvular and Pericardial Heart Disease
Sarah A. Spinler, PharmD, FCCP, FAHA, FASHP, AACC, BCPS (AQ-Cardiology), and Frank E. Silvestry, MD, FACC, FASE

SECTION VII—DRUG-INDUCED ENDOCRINE DISEASES

Chapter 30: Glucose and Insulin Dysregulation
Devra K. Dang, PharmD, BCPS, CDE, FNAP; Frank Pucino, Jr., PharmD,

MPH, FASHP, FCCP; Charles D. Ponte, PharmD, BC-ADM, BCPS, CDE, CPE, FAADE, FAPhA, FASHP, FCCP, FNAP; and Karim Anton Calis, PharmD, MPH, FASHP, FCCP

Chapter 31: Thyroid Diseases

Genevieve Lynn Ness, PharmD; Judy T. Chen, PharmD, BCPS, BCACP, CDE, FNAP; Betty J. Dong, PharmD, FASHP, FAPhA, FCCP; Frank Pucino, Jr., PharmD, MPH, FASHP, FCCP; and Karim Anton Calis, PharmD, MPH, FASHP, FCCP

Chapter 32: Hypothalamic, Pituitary, and Adrenal Diseases

Andrew Y. Hwang, PharmD, BCPS; Steven M. Smith, PharmD, MPH, BCPS; and John G. Gums, PharmD, FCCP

Chapter 33: Sexual Dysfunction in Males

Mary Lee, PharmD, BCPS, FCCP, and Roohollah Sharifi, MD, FACS

Chapter 34: Gynecologic Diseases and Infertility in Women

Judith A. Smith, PharmD, BCOP, CPHQ, FCCP, FISOPP

SECTION VIII—DRUG-INDUCED GASTROINTESTINAL DISEASES

Chapter 35: Upper Gastrointestinal Ulceration

Dianne W. May, PharmD, FCCP, BCPS; Micaela Carroll, PharmD, BCPS; and J. Russell May, PharmD, FASHP

Chapter 36: Diarrhea

Sarah A. Nisly, PharmD, BCPS, FCCP, and Alison M. Walton, PharmD, BCPS

Chapter 37: Constipation

Sarah A. Nisly, PharmD, BCPS, FCCP, and Carolyn M. Jung, PharmD, BCPS

Chapter 38: Hepatic and Cholestatic Diseases

Scott S. Malinowski, PharmD, and Daniel M. Riche, PharmD, FCCP, BCPS, CDE, ASH-CHC, CLS

Chapter 39: Pancreatitis

Pramodini B. Kale-Pradhan, PharmD, and Sheila M. Wilhelm, PharmD, FCCP, BCPS

Chapter 40: Nausea and Vomiting

Saeed K. Alzghari, MS, MBA (HOM), PharmD, BCPS; Bonnie A. Labdi, PharmD, BCOP; and Jon D. Herrington, PharmD, BCPS, BCOP

SECTION IX—DRUG-INDUCED DISEASES OF THE KIDNEY AND FLUID & ELECTROLYTE DISORDERS

Chapter 41: Acute Kidney Injury

Amy Barton Pai, PharmD, BCPS, FASN, FCCP, FNKF, and Nicole M. Wegrzyn, PharmD, BCACP

Chapter 42: Chronic Kidney Disease

Mary K. Stamatakis, PharmD

Chapter 43: Syndrome of Inappropriate Antidiuretic Hormone Secretion and Diabetes Insipidus

Mark A. Malesker, PharmD, FCCP, FCCM, FASHP, BCPS, and Daniel E. Hilleman, PharmD, FCCP

Chapter 44: Acid–Base Disorders

Lori D. Wazny, BSc(Pharm), PharmD, EPPh; J. Christine Davis, BSc(Pharm), PharmD, ACPR; and Robert E. Ariano, PharmD, BCPS, FCCM

SECTION X—DRUG-INDUCED HEMATOLOGICAL DISORDERS

Chapter 45: Bleeding Disorders

Tiffany Pon, PharmD, BCPS, and Jaekyu Shin, PharmD, MS, BCPS

Chapter 46: Thrombocytopenia

Kellie Jones Weddle, PharmD, BCOP, FCCP, FHOPA, and Patrick J. Kiel, PharmD, BCPS, BCOP

Chapter 47: Thromboembolic Diseases

Candice L. Garwood, PharmD, FCCP, BCPS, BCACP

Chapter 48: Neutropenia and Agranulocytosis

Teresa C. Thakrar, PharmD, BCOP, and Christopher A. Fausel, PharmD, MHA, BCOP

Chapter 49: Anemias

LeAnn B. Norris, PharmD, BCPS, BCOP, and Charles L. Bennett, MD, PhD, MPP

SECTION XI—DRUG-INDUCED BONE, JOINT, AND MUSCLE DISEASES

Chapter 50: Osteoporosis and Osteomalacia

Laura M. Borgelt, PharmD, FCCP, BCPS, and Danielle R. Fixen, PharmD

Chapter 51: Gout and Hyperuricemia
Jasmine D. Gonzalvo, PharmD, BCPS, BC-ADM, CDE, LDE

Chapter 52: Myopathy
Craig Williams, PharmD, FLNA, BCPS

SECTION XII—MISCELLANEOUS DRUG-INDUCED DISEASES

Chapter 53: Weight Gain
Amy Heck Sheehan, PharmD

Chapter 54: Temperature Dysregulation
Susan M. Wilson, PharmD, and Ian A. Ross, PharmD

Chapter 55: Ototoxicity
Monica L. Miller, PharmD, MS

Chapter 56: Oral Manifestations of Systemically Administered Drugs
Ashley H. Meredith, PharmD, BCACP, BCPS, CDE

Chapter 57: Neoplastic Diseases
Sandra Cuellar, PharmD, BCOP, and Christina Mactal Haaf, PharmD, BCOP, BCPS

Chapter 58: Teratogenicity
Kylie N. Barnes, PharmD, BCPS

INDEX

FOREWORD

Much has changed in pharmacotherapy since the publication of the second edition of this text. New drugs have been introduced, and postmarking experience with those previously available has given us a better understanding of associated risks. In addition, patterns of medication use and drug exposure have continued to be affected by the way drugs are promoted, by reclassification of drugs from prescription to nonprescription status, by changes in drug prices, and by product shortages, which, unfortunately, have become commonplace. As a result of an aging population and other factors, more people are using more drugs today than ever before. Nearly half of Americans report having used a prescription medication in the last 30 days, and nearly a quarter used three or more. Perhaps the only things that have stayed about the same are the systems we use for prescribing, dispensing, administering, and monitoring drug therapy, which have not changed appreciably since the mid-1900s. As a consequence, drug-related morbidity and mortality is rampant. Nearly 20 years ago, Ernst and Grizzle[1] estimated that drug-related problems cost Americans more than $177 billion and were responsible for more than 200,000 deaths annually. It is unlikely that those horrifying statistics have improved in the years since.

There are numerous ways we can improve medication use. These include the reassessment of the risks and benefits of direct-to-consumer advertising; possible expansion of the authority of the U.S. Food and Drug Administration to include “nutraceuticals” and dietary supplements; a slower, more controlled launch of newly approved drugs to allow an evaluation of safety and efficacy in population subsets not thoroughly evaluated during clinical trials; more structured, broad-based programs for postmarketing surveillance; and the development of fully integrated and properly aligned systems of prescribing, dispensing, administering, and monitoring drug therapy and for educating consumers about safe and effective medication use.

Change won’t be easy (or quick); however, and, until improvements are made, individual practitioners will continue to be their patients’ best defense against drug-related morbidity or mortality—a responsibility that requires exceptional vigilance. The third edition of *Drug-Induced Diseases: Prevention, Detection, and Management* will help with that. Editors Tisdale and Miller have assembled a remarkable team of experts to serve as chapter authors and reviewers, and together they have created an essential resource for healthcare practitioners. The text uses a unique disease-oriented approach and organizes critical information in an easily retrievable format. It has been carefully updated using a standardized search strategy to include drugs introduced since the previous edition as well as new information about drugs previously marketed. Tables and figures also have been updated, where appropriate, to enhance readability and the text includes new chapters.

Drug-related morbidity and mortality is rampant. *Drug-Induced Diseases: Prevention, Detection, and Management* is an extraordinary work that continues to be the standard for understanding and preventing drug-induced diseases. It can be a practitioner's most useful tool.

PREFACE

We are very pleased to present this third edition of *Drug-Induced Diseases: Prevention, Detection, and Management*. The second edition is used throughout the United States and in 20 other countries around the world, and it is gratifying to know that the text is helping fill a previously unmet need for this type of reference.

In the preface to the first edition, readers were reminded of healthcare providers' prime directive, "First, do no harm." Although drug therapy can prolong and improve a patient's quality of life, it is important to remember that drugs are also capable of causing harm by triggering new ailments or exacerbating those that already exist. The potential benefits of drug therapy, therefore, must always be weighed carefully against the potential harm.

Unfortunately, we don't always know all the risks associated with a given drug in advance. Premarketing trials fail to identify serious adverse events in at least 20% of drugs approved by the U.S. Food and Drug Administration (see Chapters 1–5). Despite best efforts to ensure that all drugs are safe and effective, millions of patients each year develop drug-induced diseases—some previously known and some previously unknown. In the second edition's preface, readers were reminded of Heraclitus' admonition, "If you do not expect the unexpected, you will not find it." Whenever drug therapy is employed, healthcare providers must train themselves to be on the lookout for unexpected consequences.

Pharmacists, physicians, nurses, and other healthcare professionals on the front lines of patient care and pharmacotherapy must be knowledgeable about the risk of drug-induced diseases and methods of prevention, detection, and management. Students in the health professions must learn that pharmacotherapy has both benefits and risks. Every time a patient presents with a new disease or an exacerbation of an existing condition, someone needs to ask, "Could this problem be drug-induced?"

The purpose of this book is to provide a comprehensive source of information regarding the prevention, detection, and management of drug-induced diseases for current and future healthcare practitioners. Our hope is that it will also encourage practitioners to weigh the risks and benefits before initiating pharmacotherapy and to always expect the unexpected.

As in the previous editions, we consider drug-induced diseases to be a specific subset of adverse effects caused by drugs—a subset characterized by the severity of symptoms and outcomes. For the purposes of this book, we have defined a drug-induced disease as an unintended effect of a drug that results in mortality or morbidity with symptoms sufficient to prompt a patient to seek medical attention and/or require hospitalization.

The text has been structured to facilitate readers' ability to find specific information related to drug-induced diseases. Section I describes the changing regulatory, legal, and practice landscape as they relate to drug-induced diseases; provides a general overview of the epidemiology and public health impact of these conditions; discusses factors that may contribute to the development of drug-induced diseases; describes the structure and strategy of postmarketing surveillance for their detection and characterization; and provides a general approach to patient evaluation. Sections II through XII are organized around specific diseases in which drugs have been implicated as causative agents or, in some cases, the organ system that is involved.

The disease-related chapters follow a consistent structure: causative agents, epidemiology, mechanisms, clinical presentation and differential diagnosis, risk factors, morbidity and mortality, methods of prevention, management, and information for patients. Each chapter underwent blinded external review by one or more additional content experts.

Numerous changes and, we believe, significant improvements have been incorporated into this edition. Three chapters have been added: Bleeding Disorders, Teratogenicity, and Oral Manifestations of Systemically Administered Drugs. Chapters have been expanded, and information throughout has been carefully updated by the contributors. Chapter authors used a structured and more consistent literature search strategy to ensure relevant information was not inadvertently overlooked.

As in previous editions, each chapter includes a series of standard tables, which are in a consistent format throughout. All of the "Agents Implicated" tables include an indication of the strength of the evidence (Level of Evidence) that links a listed drug to a specific drug-induced disease:

- **Level of evidence A** has been assigned when there is evidence of causality from one or more randomized, controlled clinical trials.
- **Level of evidence B** indicates that there is evidence of causality from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses, and/or postmarketing surveillance studies.
- **Level of evidence C** has been assigned when evidence of causality is from one or more published case reports or case series.

Undertaking a book such as this is not an easy task, and we gratefully acknowledge the work of the chapter authors and expert external content reviewers. Without their significant contributions, this book could not have been completed. We also want to express our appreciation for the assistance of the ASHP staff. We sincerely hope that this text helps practitioners as they work to continually improve patient outcomes related to drug therapy.

MAGNITUDE/SIGNIFICANCE OF DRUG-INDUCED DISEASES: IMPACT ON THE HEALTHCARE SYSTEM

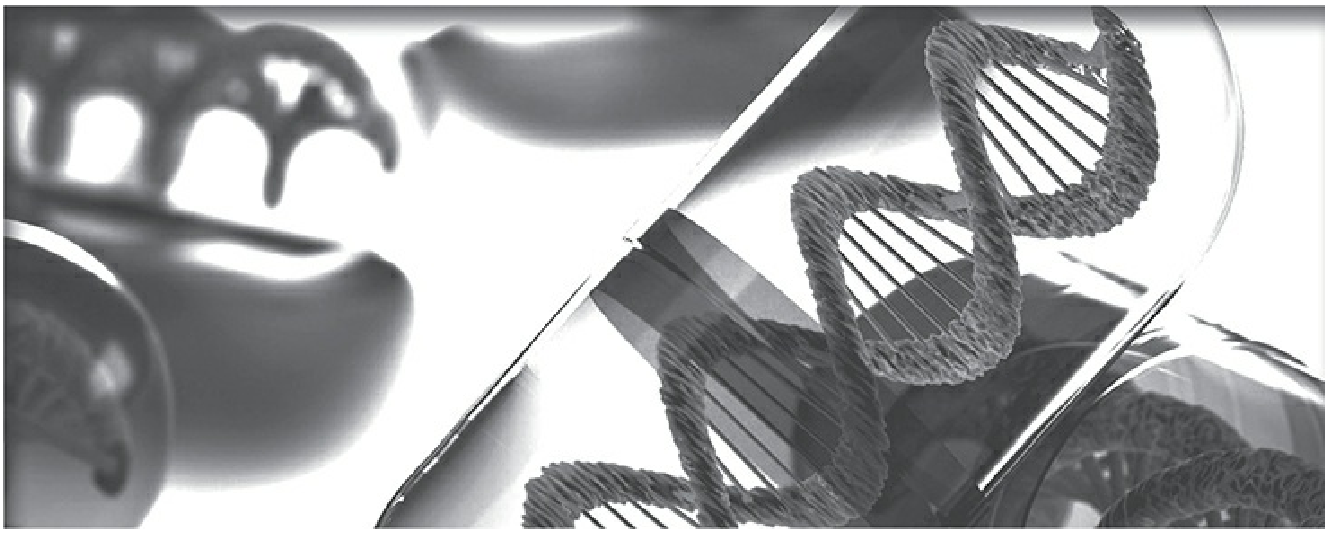
CHAPTER 1 Drug Safety and Drug-Induced Diseases:
The Regulatory, Legal, and Practice Environments

CHAPTER 2 Epidemiology and Public Health Impact of Drug-Induced Diseases

CHAPTER 3 Factors Contributing to Drug-Induced Diseases

CHAPTER 4 Postmarketing Surveillance for Drug-Induced Diseases

CHAPTER 5 Evaluating Patients for Drug-Induced Diseases



CHAPTER 1

Drug Safety and Drug-Induced Diseases: The Regulatory, Legal, and Practice Environments

Cynthia Reilly

The regulatory, legal, and practice environments in healthcare surrounding drug safety have been the subject of much scrutiny in recent years. In the early 2000s, the highly publicized market withdrawal of widely used drug products, including rofecoxib (Vioxx) and troglitazone (Rezulin) for safety reasons served as a focal point of concerns about the effectiveness of the U.S. drug approval and safety surveillance systems.[1] Eleven new drug and biologic products approved by the U.S. Food and Drug Administration (FDA) between 1996 and 2012 were withdrawn from the U.S. market between the time of approval and 2013.[2] This represents roughly 2% of the 522 products approved during this period. With the exception of drotrecogin alfa (Xigris), which was withdrawn for failing to demonstrate improved outcomes in patients with septic shock, these products were withdrawn for safety reasons that included cardiac and liver effects and opportunistic infections.

Other safety-related regulatory actions (e.g., labeling changes, such as the addition of precautions, contraindications, or black box warnings) are far more common and, although less publicized, have the potential for significant impact on patient safety if these therapies are not properly managed. Among the 522 therapies evaluated in a study encompassing the time period 1996–2012, 180 received a boxed warning either premarket or postmarket.[2] Of these, 105 products received a boxed warning as part of the preapproval review process, and 50 received a boxed warning postapproval based on safety concerns that arose after the products were marketed. Both premarket and postmarket boxed warning information was issued for 25 of the 522 products for which labeling histories were evaluated. Other adverse events associated with medication therapy, such as medication errors, have also heightened awareness among healthcare professionals, policymakers, and other stakeholders concerning all aspects of drug safety.[3] Consumers have also expressed concern, with one survey finding that 71% of respondents had either high or moderate concern about themselves or a family member being harmed by a medication error during hospitalization.[4] As medication experts, pharmacists play a critical role in ensuring drug safety through their activities in selecting and monitoring drug therapy, communicating risk versus benefit to patients to allow for informed decision making, and reporting suspected adverse drug events and drug-induced diseases.

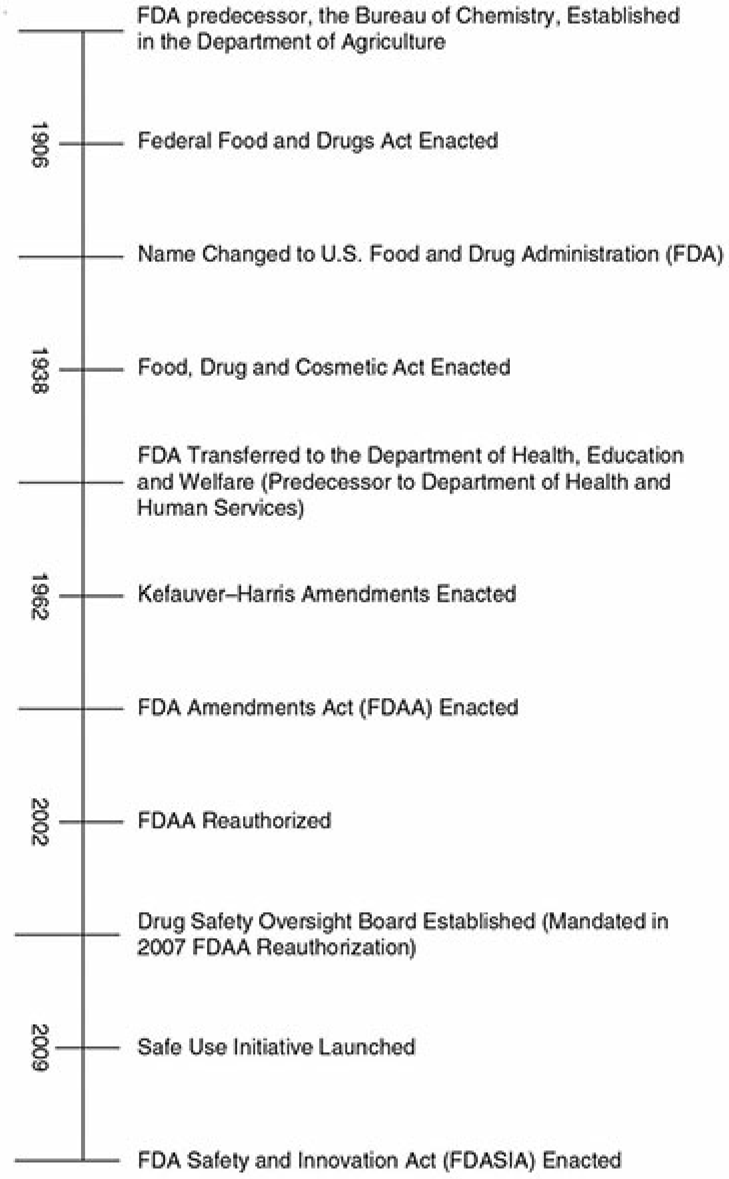
The extent of adverse drug events, which includes but is not limited to drug-induced diseases, is staggering. The FDA’s Adverse Event Reporting System (AERS) receives approximately 500,000 reports every year from prescribers, pharmacists, nurses, patients, and others.[5] In total, since its inception in 1969, the system has received roughly 5 million reports. In 2015, the FDA issued 19 public health advisories (i.e., descriptions of safety concern with recommended actions) concerning drug and biologic products.[6] However, it has been reported that 10% or less of the adverse events that occur are reported to this spontaneous reporting system.[7]

Drug-induced disease can result from unanticipated or anticipated drug effects. Disease also can occur from product impurities, as was the case with deaths attributed to the use of contaminated heparin in 2008.[8] Vigilance on the part of regulatory authorities, drug manufacturers, clinicians, and patients is necessary to minimize the potential for harm that is inherent in drug use.

DRUG SAFETY: THE REGULATORY ENVIRONMENT

THE FDA AND REGULATORY EFFORTS TO ENSURE DRUG SAFETY

Until 2007, FDA efforts to provide drug safety had largely focused on premarket strategies. However, as the history of the agency demonstrates (Figure 1–1), much of the FDA’s regulatory authority was created in response to harm, or concern for harm, associated with drugs already on the market.[9] The origins of the FDA can be traced back to the late 1860s, when its predecessor, the Bureau of Chemistry, was established as part of the Department of Agriculture. Over the years, there were repeated attempts to introduce legislation to address concerns about adulterated drug products from overseas. However, it was not until 1906, when the Federal Food and Drugs Act was passed, that the focus of the agency shifted from scientific to regulatory activities. Although that legislation permitted regulation of drug product labeling, the impetus for the law was not drug safety but rather concerns for *food* safety, which were prompted by Upton Sinclair’s *The Jungle*. The novel exposed unsanitary conditions in the meatpacking industry, which at the time were considered the greater threat to public safety.



FDA predecessor, the Bureau of Chemistry, Established in the Department of Agriculture
1906
Federal Food and Drugs Act Enacted
Name Changed to U.S. Food and Drug Administration (FDA)
1938
Food, Drug and Cosmetic Act Enacted
FDA Transferred to the Department of Health, Education and Welfare (Predecessor to Department of Health and Human Services)
1962
Kefauver–Harris Amendments Enacted
FDA Amendments Act (FDAA) Enacted
2002
FDAA Reauthorized
Drug Safety Oversight Board Established (Mandated in 2007 FDAA Reauthorization)
2009
Safe Use Initiative Launched
FDA Safety and Innovation Act (FDASIA) Enacted

FIGURE 1-1. History of U.S. Food and Drug Administration Drug Safety Activities and Regulations[9]

It wasn't until enactment of the Food, Drug, and Cosmetic Act in 1938 that legislation began to focus on premarket drug safety. Once again, this authority was granted in response to a safety incident in which an antifreeze-like ingredient in the elixir sulfanilamide resulted in more than 100 deaths.[9] In 1962, the Kefauver–Harris Amendments to the 1938 Act introduced a requirement to demonstrate both efficacy and safety prior to drug approval. This was the first legislation that focused on adverse events caused by active ingredients and was spurred by reports of birth defects following the use of thalidomide abroad. Severe malformations, including a flipper-like appearance of limbs caused by very short or absent long bones, resulted in withdrawal of the drug from worldwide markets. A U.S.-based drug manufacturer had applied for, but never received, approval to market the drug in the United States.

Significant efforts to improve drug safety have been addressed within the FDA Amendments Acts (FDAAs) of 1992, 1997, 2002, 2007, and 2012. Most notably, the 2007 reauthorization of the act grants the FDA increased authority to request that manufacturers complete postmarketing safety studies and requires that manufacturers develop and submit risk evaluation and mitigation strategies (REMS) for all drug products for which they seek FDA approval.[10-12] Although patient and prescriber education programs are potential components of REMS programs, more stringent programs, such as patient and provider registries or required laboratory monitoring and reporting, may be included in a more comprehensive restrictive drug distribution system (RDDS). FDAA 2007 also requires that the FDA establish a mechanism to increase and coordinate postmarketing surveillance efforts. The requirement was addressed by the establishment of the Sentinel Initiative in 2008, which is discussed in greater detail in Chapter 4: Postmarketing Surveillance for Drug-Induced Diseases. The 2007 reauthorization also mandated the Drug Safety Oversight Board—an entity that the FDA had already created in 2005 following the market withdrawal of Vioxx—as a mechanism to advise the agency on managing and communicating information about emerging safety issues.[6] The FDA Safety and Innovation Act of 2012 (FDASIA) included a requirement that the FDA create a five-year plan to introduce a structured benefit/risk framework to be used agencywide to assess safety during the new drug approval process.[13] In addition, the agency was directed to use monies collected from user fees to assess the effectiveness of, and make improvements to, the REMS program and evaluate strategies for using data from the Sentinel System to inform regulatory actions. The law also includes a focus on increasing the safety and integrity of the drug supply chain. Although requirements in FDASIA augmented existing work to address drug safety, it also sought to expedite drug development under certain circumstances.[13] Specifically, the law called on the FDA to improve communications with pharmaceutical manufacturers engaged in drug development and to increase staff capacity and expertise to support the review of drugs for rare diseases and the use of biomarkers and pharmacogenomics for drug approval.

THE FDA'S SAFETY-RELATED REGULATORY ACTIONS

The FDA considers and may request a number of regulatory actions when a serious or life-threatening safety concern is identified for a drug. Each action has the potential to decrease or eliminate patient access to drug therapy. Therefore, decisions regarding specific courses of action must carefully balance the effectiveness of the drug, other therapeutic options for the condition being treated, the type of possible harm to patients, and the potential for its occurrence.

Regulatory options following drug approval include clinician and patient warnings, labeling changes, and product withdrawals. To increase transparency as well as consumer and clinician awareness, the Prescription Drug User Fee Act (PDUFA IV, a component of FDAA 2007 that authorizes the FDA to use fees collected from pharmaceutical manufacturers to conduct safety activities) requires the FDA to generate quarterly reports that include information on recently identified potentially serious risks and new safety information generated from the AERS database.[12,15] Introduction of this process and enhanced efforts via the MedWatch program and other FDA drug safety initiatives generate extensive amounts of safety information. Although this is beneficial, concerns have been raised about whether this information effectively reaches or is understood by target audiences, including healthcare professionals and patients.[16,17] Safety information is and always will be an evolving topic, but the FDA and professional associations such as ASHP are collaborating to determine how this information can be made available in ways that are most useful to clinicians and their patients.

In July 2012, the FDA launched the first class-wide REMS for opioids after holding a series of stakeholder meetings to discuss options to ensure that the benefits of these drugs continue to outweigh their risks.[18] The effort was in response to an alarming increase in the number of overdose deaths associated with the use of these products. According to the Centers for Disease Control and Prevention (CDC), such deaths have increased more than 300% since 1998, while prescribing rates for these drugs quadrupled between 1999 and 2010.[19] In 2014, deaths from prescription opioids reached an all-time high of roughly 19,000.[20] The REMS, which involved more than 30 products marketed by more than 20 companies, required that manufacturers modify product labeling to include a boxed warning to highlight risks; provide training to prescribers, pharmacists, and other healthcare professionals to ensure proper use; and provide educational materials to patients.[18] The extent of opioid prescribing and the morbidity and mortality associated with their use was highlighted by an advertisement during Super Bowl 50 for a drug to treat a drug-induced disease, opioid-induced constipation.[21] The promotion, which cost an estimated $10 million (based on projected costs of $5 million per 30 seconds for Super Bowl ads), drew criticism from the White House, elected officials, pain and addiction specialists, and the media, among other stakeholders. In February 2015, the FDA announced plans to extend the REMS to include immediate-release opioid products.[22]

When less stringent interventions are unable or deemed unlikely to address safety concerns, RDDS can be used to allow continued availability of drugs that are associated with significant safety concerns but provide a health benefit if used appropriately in specific patient populations. RDDS can include clinician or facility registration, patient registries that are used to track and evaluate response to therapies, and performance-linked access systems. The FDA can request that these programs be established for drugs that are already approved or as a condition for approval. For example, in 1999, the drug thalidomide, which had previously been removed from world markets, was approved in the United States for the treatment of lesions caused by Hansen disease, or leprosy.[23] However, to prevent or reduce the risk of significant drug-induced disease, thalidomide is available only via physicians and pharmacists registered in the System for Thalidomide Education and Prescribing Safety (STEPS) program. The drug cannot be prescribed for women of childbearing age, unless the patient meets certain criteria (e.g., ability to comprehend and follow pregnancy precautions). The physician must also document proof of a negative pregnancy test 24 hours prior to initiation of therapy and on an ongoing basis during therapy. Oral and printed patient education materials are also a significant component of the STEPS program.

Thalidomide is one of dozens of drugs marketed in the United States for which an RDDS is required (Table 1-1).[24] This list is expected to continue to expand based on the FDA's increased authority to require these programs under the PDUFA IV. Although these programs facilitate ongoing availability of drug therapies, they also present challenges to clinicians and patients.[25] RDDS are not currently standardized, and each drug manufacturer may establish its own management processes, including clinician registration requirements. The variability and complexity of these processes can delay or limit patient access to therapies, especially as patients move between healthcare settings. At the urging of professional organizations and others, the FDA is evaluating strategies to minimize unintended consequences of these programs on continuity of care and patient access to these high-risk drugs.

Table 1-1 FDA-Approved Drugs with RDDS[24]

Drugs

- α1-proteinase inhibitor
- Alemtuzumab[a]
- Alosetron
  - o Avelumab
- Alvimopan
- Ambrisentan
  - o Axicabtagene
- Bosentan
- Buprenorphine and buprenorphine/naloxone fixed dose
  - o Brodalumab
- Cabozantinib
- Carfilzomib
- Carglumic acid
- Ceritinib
- Cisapride[a]
- Clofazimine[a]

- Clozapine
- Collagenase clostridium histolyticum
- Cysteamine
- Dalfampridine
- Deferasirox
- Deferiprone
  - o Deutetrabenazine
- Diphtheria antitoxin (equine)
- Dofetilide
- Droxidopa
- Eculizumab
  - o Fentanyl (transmucosal immediate-release and iontophoretic transdermal formulations)
  - o Flibanserin
- Gefitinib
- Ibritumomab
- Iloprost
- Isotretinoin
- Lenalidomide
- Lenvatinib
- Lomitapide
- Macitentan
- Mifepristone
- Mipomersen
- Natalizumab
  - o Obeticholic acid
- Olanzapine
- Olaparib
- Panobinostat
- Pertuzumab
- Pomalidomide
- Riociguat
- Ruxolitinib
- Sodium oxybate
- Taliglucerase alfa
- Tasimelteon
- Teduglutide
- Tegaserod
- Tetrabenazine
- Thalidomide
- Treprostinil
- Vandetanib
- Vemurafenib
- Vigabatrin

FDA = U.S. Food and Drug Administration, RDDS = restricted drug distribution systems.
aDrug is available only through established compassionate-use programs.

A significant challenge to the FDA drug approval process is the need to balance safety with more rapid access to innovative and life-saving therapies. Expedited pathways have been developed to meet these objectives.[26] To qualify for these programs—which include fast-track designation, breakthrough therapy designation, accelerated approval, and priority review designation—a drug must meet specific requirements. These include that the drug must (1) address an unmet medical need,

(2) provide benefit over available drug treatments, and (3) be used in the treatment of a serious or life-threatening condition. The breakthrough therapy category that was created as part of FDASIA has, as intended, increased the rate of submission and approval of medications with preliminary studies indicating superior efficacy in treating serious conditions compared to existing treatments. From fiscal year (FY) 2012 through FY 2017, the FDA received 500 applications for breakthrough therapies.[27] Of these, 191 applications were granted, 244 were denied, and 65 were withdrawn from consideration. Although this change has been welcomed by many, others have raised concerns that, even though these pathways do not change the standards of quality for evidence required for drug approval, they do alter the extent of evidence that is necessary to demonstrate efficacy and safety.[28]

Often, expedited drug approvals are based on surrogate markers, with requirements for postmarketing safety evaluations to identify adverse events that either did not appear, or could not be fully characterized, during the drug approval process. Historically, the FDA had been criticized for failure to ensure drug manufacturers' timely and adequate compliance with postmarketing requirements. This was, in part, due to the inability to enforce these requirements. With the 2007 reauthorization of FDAA, the agency secured the authority to require studies and impose sanctions if timelines and goals were not met. However, to date, the impact of this change has been limited. An evaluation comparing the status of postmarketing studies between 2007 and 2011 found that the proportion of pending studies (i.e., those not initiated but not yet behind the agreed-upon schedule) decreased from roughly 57% to 44%.[29] However, the proportion of delayed studies (those behind schedule) doubled from 6.8% in 2007 to 13.5% in 2011. When only those studies included under the 2007 FDAA change were considered, 15% of studies were pending and just over 1% were delayed. To a great extent, the lower percentages for FDAA-required studies reflect the fact that these processes had only recently been initiated (i.e., the timelines for these commitments were likely in initial stages and therefore unlikely to be included in the delayed category).

The recent trend toward shorter time frames for drug approval has been criticized as a significant contributor to drug safety problems, but this perception is misleading because it implies a direct cause-and-effect relationship between shortened average time to drug approval and drug withdrawals or other safety issues. Safety concerns can arise throughout a product's life cycle.[30] An example is aprotinin, an antithrombotic agent that was used in cardiac surgery for 14 years before accumulating reports of increased morbidity and mortality resulted in its voluntary withdrawal from the U.S. market in late 2007.[31]

An FDA assessment of the timing of safety-related actions for 444 new molecular entities (NMEs) approved between 1991 and 2006 demonstrated that regulatory actions occur throughout a product's life cycle.[32] Among drugs that the FDA approved during that time period, 78% were associated with at least one safety-related action and 3% were withdrawn from U.S. market. A subanalysis of drugs approved from 1991 through 1995 (i.e., representing drugs that were marketed for a minimum of 13 years) found that 27% of NMEs underwent changes or additions to boxed warnings, warnings, or precautions sections of the FDA-approved labeling. No drugs in this subgroup were removed from the market. For drugs marketed less than 5 years (i.e., those approved from 2003 through 2006), 44% underwent safety-related labeling changes, and there were no market withdrawals. These data demonstrate that safety actions occur on an ongoing basis and that newer drugs are not necessarily more prone to safety issues. Rather, it is likely that new safety signals are generated throughout the life cycle of a drug.

DRUG SAFETY IN THE LEGAL ENVIRONMENT

Drug safety has been the subject of countless court rulings, with most cases focusing on who is responsible for ensuring the safe use of drug products—pharmaceutical manufacturers, prescribers, other healthcare professionals, or a combination of these entities. A summary of cases involving pharmaceutical manufacturers and pharmacies is provided in Table 1-2.

PHARMACEUTICAL MANUFACTURERS

State and federal courts have commonly found pharmaceutical manufacturers to be the primary entity responsible for drug safety. Historically, there has been substantial litigation against pharmaceutical manufacturers alleging that they hid, misrepresented, or otherwise failed to meet the obligation to inform clinicians and patients regarding known or suspected risks associated with a drug's use. In *Feldman v. Lederle Laboratories* (1984), one of the more unusual cases, the New Jersey Supreme Court ruled in favor of plaintiff Feldman, who claimed that the drug manufacturer failed to provide sufficient information and warnings to physicians about the potential for tooth discoloration associated with its tetracycline product, demeclocycline.[33] Ms. Feldman was prescribed and dispensed samples of the drug by her father, a physician and pharmacist, several times when she was an infant and toddler. The company claimed that at the time Ms. Feldman received demeclocycline, information about this adverse effect was not fully known, and therefore not included in the labeling and prescribing information approved by the FDA. However, abnormalities in tooth development and discoloration associated with tetracycline products had been reported previously in published studies of laboratory animals and children with cystic fibrosis who received high doses. A lower court had found the manufacturer not liable because the company had asked the FDA for guidance on whether to include a warning in the labeling of all of its tetracycline products, but the agency advised against including this information in demeclocycline labeling based on a lack of sufficient evidence. However, the state supreme court disagreed with the lower court's decision, noting that the FDA's response did not prevent the manufacturer from providing this information or relieve the company of its responsibility to do so. There are several unusual circumstances in this case, including uncertainty as to whether Ms. Feldman received demeclocycline or another tetracycline. Because samples were used, no prescription or dispensing records were available to confirm the plaintiff's assertion. In addition, most product liability cases include the manufacturer and prescriber as litigants, but in this instance, legal action was directed only toward the drug manufacturer, not the prescriber (the patient's father).

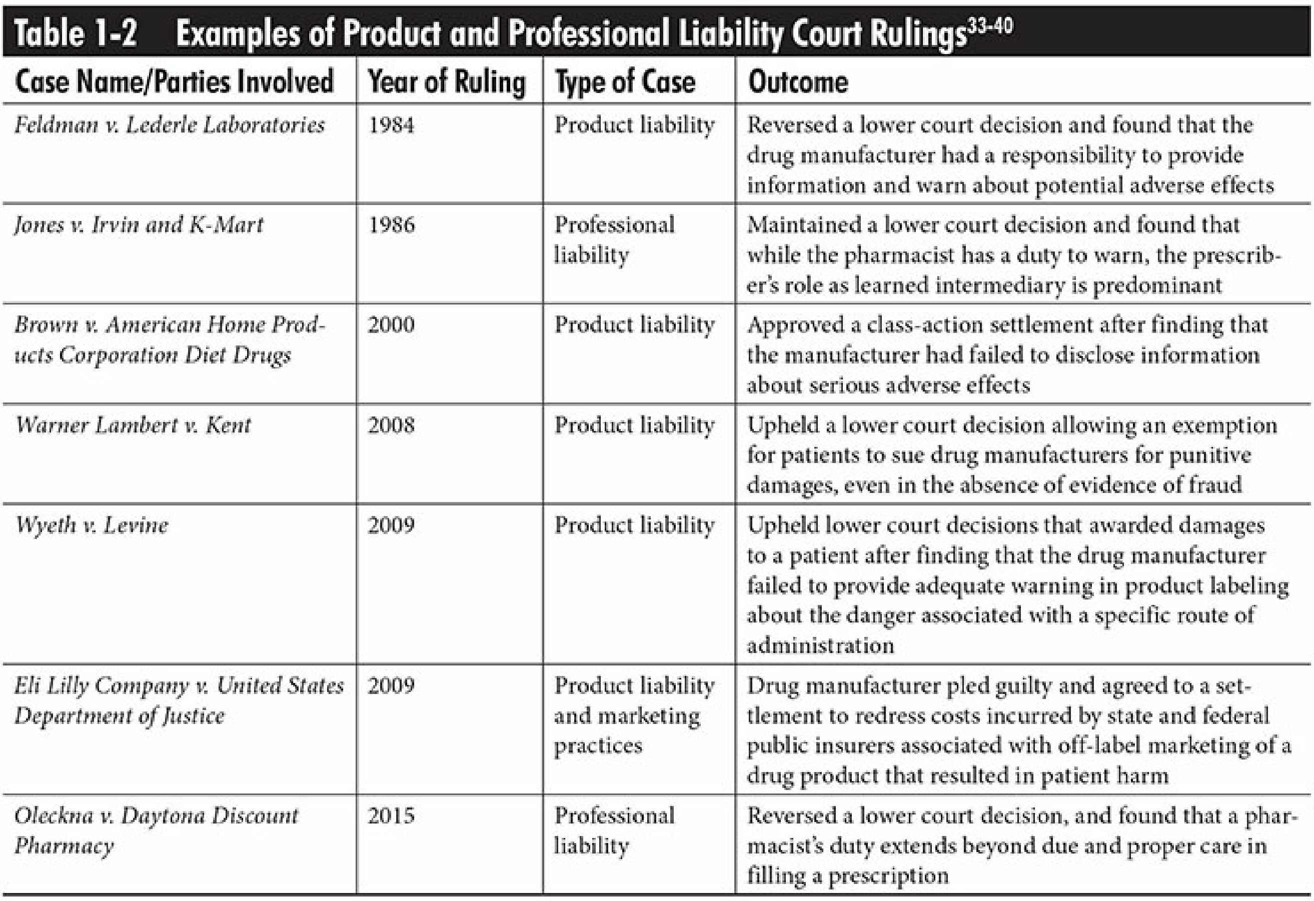


Table 1-2 Examples of Product and Professional Liability Court Rulings[33-40]

Case Name/Parties Involved	Year of Ruling	Type of Case	Outcome
Feldman v. Lederle Laboratories	1984	Product liability	Reversed a lower court decision and found that the drug manufacturer had a responsibility to provide information and warn about potential adverse effects
Jones v. Irvin and K-Mart	1986	Professional liability	Maintained a lower court decision and found that while the pharmacist has a duty to warn, the prescriber's role as learned intermediary is predominant
Brown v. American Home Products Corporation Diet Drugs	2000	Product liability	Approved a class-action settlement after finding that the manufacturer had failed to disclose information about serious adverse effects
Warner Lambert v. Kent	2008	Product liability	Upheld a lower court decision allowing an exemption for patients to sue drug manufacturers for punitive damages, even in the absence of evidence of fraud
Wyeth v. Levine	2009	Product liability	Upheld lower court decisions that awarded damages to a patient after finding that the drug manufacturer failed to provide adequate warning in product labeling about the danger associated with a specific route of administration
Eli Lilly Company v. United States Department of Justice	2009	Product liability and marketing practices	Drug manufacturer pled guilty and agreed to a settlement to redress costs incurred by state and federal public insurers associated with off-label marketing of a drug product that resulted in patient harm
Oleckna v. Daytona Discount Pharmacy	2015	Professional liability	Reversed a lower court decision, and found that a pharmacist's duty extends beyond due and proper care in filling a prescription

In *Brown v. American Home Products Corporation Diet Drugs*, the federal courts approved a negotiated settlement in the class-action product liability case of fenfluramine–phentermine ("fen-phen") or dexfenfluramine with phenteramine.[34] The class-action lawsuit found that product manufacturers for fenfluramine (marketed as Pondomin by American Home Products, Inc.) and dexfenfluramine (marketed as Redux by Wyeth) possessed extensive information, including published case reports, animal studies, case reports in patients taking drugs with similar effects on serotonin, and unpublished studies conducted by the manufacturer, showing that the drugs could cause damage to heart valves and lead to valvular regurgitation. The court found that despite having this information, the manufacturer continued to market the drug combination until the drugs were withdrawn from the market in 1997, without further investigating these reports or warning prescribers or patients through labeling or other mechanisms. The settlement created a $2.5 billion fund to compensate patients for harm and cover current and future associated healthcare costs based on factors such as length of therapy and extent of harm.

A 2001 U.S. Supreme Court case ruled that patients cannot sue pharmaceutical companies for withholding information during the drug approval process in instances in which the FDA has found no evidence of fraud or failure to disclose information. However, in *Warner Lambert v. Kent*, a split decision by that court upheld a lower court decision allowing an exemption in Michigan law that permitted patients who had received troglitazone to sue the product manufacturers for punitive damages by alleging fraud, even in instances when the FDA did not allege or find evidence of fraud.[35] Similar exemptions exist in seven other states.

A U.S. Supreme Court decision in March 2009 set a precedent that may affect future cases that involve how pharmaceutical manufacturers view and operationalize their duty to warn of significant adverse drug events in product labeling. In *Wyeth v. Levine*, the court upheld a state trial and supreme court decision that awarded damages to a Vermont woman whose arm was amputated because of gangrene that developed following administration of promethazine by intravenous (IV) push.[36] The product's FDA-approved labeling included information on the preferred route of administration (deep intramuscular injection), warnings about the potential for gangrene (especially with intraarterial or subcutaneous administration), and a preference for administration via continuous IV infusion rather than rapid push when the drug is administered via IV. However, the trial court found that the patient's injuries would not have occurred if the product's labeling included adequate warning, including specific information about the danger of IV push administration. The U.S. Supreme Court agreed with the trial court and disagreed with the pharmaceutical manufacturer's argument that it was protected from state law claims because of federal labeling requirements and the FDA's approval of the existing product's label. In general, those requirements allow a manufacturer to change labeling only following FDA approval of the proposed change. However, the court noted that the manufacturer could have strengthened the safety warning through the "Changes Being Affected" regulation, which allows labeling changes that improve safety while the manufacturer is in the process of seeking the FDA's official approval of that change. In issuing its decision, the court emphasized that the pharmaceutical manufacturer, not the FDA, is ultimately responsible for the accuracy and completeness of the product labeling and that the FDA's regulatory authority is intended to be complementary to, not pre-emptive of, a state's role in drug safety. This decision may have a far-reaching impact on other ongoing product liability cases.

In 2009, Eli Lilly, manufacturers of the drug olanzapine (Zyprexa), pled guilty to misdemeanor criminal charges of promoting the drug for off-label use brought by the U.S. Department of Justice.[37] The settlement of $1.415 billion, included a criminal fine of $515 million and up to $800 million to settle civil lawsuits with the federal government and the states to redress costs associated with off-label promotion that resulted in payments from Medicaid and federal programs for unapproved uses, including dementia and psychosis associated with Alzheimer disease in assisted-living nursing home residents. This amount was in addition to state-based consumer protection lawsuits that were resolved in 2008, when Lilly agreed to pay $62 million to 33 states.

PHARMACISTS' AND OTHER CLINICIANS' DUTY TO WARN

According to the National Association of Chain Drug Stores, as of March 2015 there have been approximately 125 state and federal lawsuits involving the pharmacist's duty to warn.[38] The majority of these cases have found that pharmacists are not liable for patient harm resulting from adverse drug events or drug-induced disease. These decisions are generally based on the learned intermediary doctrine, which assigns responsibility for drug selection to the prescriber based on his or her knowledge of the drug and the individual patient. Pharmacists have generally been considered "sellers" of the drug product or service, and the courts have considered dispensing to be an extension of the physicians' order. Several decisions have noted that if pharmacists' liability was permitted, it could undermine the physician–patient relationship by calling prescribers' authority into question.[41] Based on existing case law, it is unclear how the learned intermediary doctrine would be applied to pharmacists who select drug therapy under collaborative practice agreements or with the significant expansion of information that would be available to pharmacists from proposed national or universal electronic health records. In *Jones v. Irvin and K-Mart*, the plaintiff appellate argued that the practice of pharmacy had changed dramatically, that the pharmacist had greater knowledge of the dangers associated with drugs than physicians and, therefore, the pharmacists' duty to warn warranted new consideration. The court found that while this advanced knowledge may be true, the physician's role as learned intermediary is predominant.[39] However, in *Oleckna v. Daytona Discount Pharmacy* in 2015, Florida's 5th circuit court of appeals reversed a lower court ruling that a pharmacist could not be held negligent for a death that occurred after a patient overdosed on a combination of opioids and alprazolam.[40] The plaintiff asserted that the pharmacist allowed the patient to repeatedly receive refills before the supply of drug from previous prescriptions was exhausted. In allowing a civil lawsuit to proceed, the court stated, "We refuse to interpret a pharmacist's duty to use 'due and proper care in filling the prescription' as being satisfied by 'robotic compliance' with the instructions of the prescribing physician." These two cases highlight the fact that courts are beginning to take a more expansive view of the pharmacist's role.

Although the learned intermediary principle has frequently shielded pharmacists and their employers from liability, it negatively affects efforts to establish pharmacists as medication experts and independent practitioners. Most importantly, pharmacists have a professional obligation to ensure safe care, regardless of legal liability. Patient education, including risk communication, is a significant component of the commitment that all pharmacists make through their education, licensure, and subsequent practice.

THE DRUG APPROVAL PROCESS AND OTHER FACTORS THAT AFFECT DRUG-INDUCED DISEASE

The drug approval process is expected to assess the efficacy and, to a certain extent, the safety of new drug products, but it should be noted that several characteristics of that process and the subsequent environment of drug use contribute to drug-induced disease. Patient populations in preapproval clinical trials are, by necessity, narrowly structured and defined. Strict inclusion and exclusion criteria often exclude patients with multiple diseases and advanced disease and patients of a certain sex, age, or race. Even the largest clinical trial conducted across multiple study sites evaluates a drug's use in a number of patients that is small in comparison with that following broader use of the drug postapproval—use that includes individuals with characteristics not studied during the approval process.

Drug-induced disease can also be attributed to conditions of drug use postapproval, which can differ dramatically from established conditions in clinical studies. An evaluation that linked outpatient dispensing and diagnosis information for 160 commonly prescribed drugs found that 21% of drug use was for off-label indications (i.e., did not match indications listed in the FDA-approved labeling).[42] Further, 73% of this off-label use was considered to be based on little or no scientific evidence. Subtle changes in manufacturing processes can also contribute to drug-induced diseases. For example, between 1998 and 2001, there was a dramatic increase in the number of pure red-cell aplasia (PRCA) cases in patients with chronic kidney disease.[43,44] PRCA is a known, but very rare, adverse effect that can occur when antierythropoietin antibodies form in response to erythropoietin treatment. Most events occurred in patients treated with an erythropoietin product supplied by one manufacturer, but cases also occurred in patients treated with a similar product. On further analyses, the dramatic increase in adverse events was attributed to a change in the stabilizers in one manufacturer's product and subsequent storage, handling, and subcutaneous administration of that product. Education regarding proper use of the various formulations resulted in a significant decrease in the number of PRCA cases.

Product contamination has also resulted in significant morbidity and mortality. One example is the case of serious adverse events associated with heparin that occurred from November 2007 through February 2008.[8,45] Adverse events included 62 deaths, with other reports of patients experiencing allergic symptoms or symptomatic hypotension. Voluntary product recalls occurred when a pattern of serious events was determined. The adverse drug events were later linked to the presence of oversulfated chondroitin sulfate in the active pharmaceutical ingredient from an overseas plant that processed heparin from pig intestines. The contaminant was not detected in random sampling of manufacturing plants, in part because it mimics heparin in commonly used tests. FDA-conducted follow-up tests found that the contaminant accounted for 5–20% of the total mass of each sample tested. It was alleged that the contamination with chondroitin was a purposeful act.[46] Plans to increase overseas inspections and to modify current standards for assessing the purity of heparin were also announced. This incident illustrated the importance of oversight and inspection of the complete product development process, including assessment of the raw materials. It also noted that even in a more robust system of inspections, purposeful adulteration may occur at any time by unscrupulous suppliers of raw materials and manufacturers, as well as criminal acts by private citizens, as occurred with acetaminophen adulteration in the early 1980s. Since passage of FDASIA, the FDA has taken substantial steps to improve the safety of an increasing global supply chain, including clarifying the agency's inspection authority and increasing penalties for adulterated and counterfeit drugs.[14]

RECOMMENDATIONS TO IMPROVE DRUG SAFETY

In recent years, a number of public and private entities have assessed drug safety efforts in the United States and made recommendations for improvements. Many of these recommendations, such as development of a national database for enhanced collection and assessment of reports of adverse drug events and drug-induced diseases, were included in PDUFA IV, and their implementation is complete or well underway. The following describes major reports and the current status of their recommendations.

NATIONAL ACADEMY OF MEDICINE

In its landmark 2006 report, *The Future of Drug Safety: Promoting and Protecting the Health of the Public*, the National Academy of Medicine (formerly the Institute of Medicine) issued more than two dozen recommendations to improve drug safety.[47] The report, which focused on postmarketing safety, identified structural and procedural barriers at the FDA that hampered efforts to enhance drug safety.

The report stated that preapproval data are inherently limited in their ability to identify infrequent adverse events and that existing approaches for data collection following drug approval are not adequate to address this shortcoming. The report's authors called for increased proactive postmarketing surveillance by the FDA, as well as additional authority for the FDA to control manufacturers' postapproval marketing activities. Many of the academy's recommendations, including strengthened authority to require REMS, were included in PDUFA IV. Strategies to better inform the public, such as establishment of an advisory committee to address communication of risks, have also been implemented. However, the recommendation to prevent potential harm by restricting direct-to-consumer advertising for a period of 2 years following drug approval and requiring that labeling and marketing materials for these products contain a symbol to designate the recent approval status, were controversial and not addressed in the reauthorization of the legislation. Other National Academy of Medicine reports, including *Preventing Medication Errors* (2006) and *Knowing What Works in Health Care: A Roadmap for the Nation* (2008), have also addressed drug safety.[3,48] Although these reports focus on the broader context of avoidable harm from drug therapies and comparative effectiveness, respectively, they include components on drug-induced disease and postmarketing safety surveillance.

GOVERNMENT ACCOUNTABILITY OFFICE

In 2006, the Government Accountability Office (GAO) issued the report, *Drug Safety: Improvement Needed in FDA's Postmarket Decision-Making and Oversight Process*, which evaluated drug safety processes based on an assessment of regulatory actions for four drugs: leflunomide (Arava), cerivastatin (Baycol), valdecoxib (Bextra), and cisapride (Propulsid).[1] Leflunomide remains available in the United States, but the other drugs were withdrawn voluntarily from the U.S. market following several safety assessments by FDA staff and subsequent regulatory actions. A major finding in the GAO report was instances in which divisions within FDA's Center for Drug Evaluation and Research (CDER) made conflicting recommendations. As a result, decisions were either not made or were made counter to the recommendations of another FDA group without a clear process for resolving the disparate views.

The GAO identified a lack of collaboration and communication between what were then the two predominant offices involved in drug safety—the Office of New Drugs (OND), which is responsible for drug approval and for initiating regulatory actions, and the Office of Drug Safety (ODS), which predominantly focused on postmarketing safety. The GAO described the ODS as serving in an advisory capacity to the OND, based on its finding that the ODS had no authority to initiate a regulatory action. The report identified a lack of documented processes for decision-making, including an absence of criteria to determine the appropriate regulatory action when a safety concern is identified.

Since that time, significant progress has been made to address shortcomings identified in the GAO report, including consolidation of safety efforts under the Office of Surveillance and Epidemiology, which is charged with identifying drug safety concerns and recommending actions to improve product safety and protect the public health.[49] In 2007, the CDER launched the Document Archiving, Reporting, and Regulatory Tracking System (DARRTS) system, which facilitates sharing of information about drugs with significant safety concerns across the numerous divisions within the agency.[50] In 2012, the agency also proposed a framework for prioritizing drugs that are tracked in DARRTS. Once identified, FDA staff designate the concern as standard, priority, or emergency based on an assessment of factors that include the size of the population affected and the theoretical frequency of harm. Modulating factors, including the extent and quality of evidence indicating a potential harm and the availability of alternative treatments are also considered. With this work, the FDA has taken substantial steps to address the concerns highlighted in the GAO report that focus on the lack of criteria and processes. However, it should be noted that risk assessment and decisions about drug safety are not an exact science and require careful balancing of the advantages and disadvantages of providing continued availability of a drug, which is based on evidence that, by nature, is constantly evolving.

OFFICE OF THE INSPECTOR GENERAL

In 2013, the Office of the Inspector General (OIG) for the Department of Health and Human Services completed an assessment of the effectiveness of REMS and issued seven recommendations to address shortcomings identified in the agency's processes to monitor these programs.[51] The study, which reviewed drug manufacturers' submission and subsequent FDA assessment of 49 of the 99 REMS that were in place in 2012, found that the FDA determined nearly half of the submissions were incomplete. Further, only seven of the submissions that were reviewed met all goals established by the FDA, according to the agency's own assessment of submitted reports. A common reason for failing to meet established goals was a documented lack of patient or prescriber awareness of potential harm. In other instances, the FDA assessment found that information was lacking to determine if this goal was met either because surveys were not conducted or due to shortcomings in survey design or implementation (e.g., small sample size, patient selection not representative of the target population). The OIG recommendations included developing plans to assess and validate REMS assessments submitted by manufacturers, identify incomplete sponsor submissions and work with sponsors to clarify expectations and ensure timely submissions, and take steps to ensure safety in instances where REMS are not meeting established goals. The OIG also recommended that the agency seek legislative authority to enforce FDA assessment plans. At the time this report was issued, some OIG-recommended improvements were already underway as part of the FDA's REMS Integration Initiative.[52] This initiative, which was introduced in 2011, includes a goal of improving the standardization and assessment of REMS.

FDA

In addition to the activities described above, the FDA has also assessed existing processes and taken numerous steps to enhance drug safety. In late 2007, the FDA's Science Board Subcommittee on Science and Technology published a document entitled, *FDA Science and Mission at Risk: Report of the Subcommittee on Science and Technology*.[53] The report was requested by then Commissioner Andrew von Eschenbach to review the adequacy of the agency's science and technology resources to meet current and future challenges. The report concluded that the agency's resources had diminished, despite an increase in responsibilities that resulted from the speed of scientific discoveries, increased and more complex products, and the increasingly global nature of the pharmaceutical industry. The subcommittee recommended that the existing deficits in scientific research programs; recruitment, development, and retention of expert staff; and information technology must be corrected to meet these challenges.

Among the report's specific recommendations was the need to strengthen and coordinate the science program across the FDA's centers. The need for collaboration was identified with external scientific and research programs, including the Agency for Healthcare Research and Quality's Centers for Education and Research on Therapeutics, the CDC, the National Institutes of Health, and others when the expertise is not available at the FDA. It is anticipated that the Reagan–Udall Foundation, an independent not-for-profit organization mandated by PDUFA IV, will assist in the development of these and other public–private partnerships as part of its charge to assist the FDA in modernizing its activities to address the rapid pace of change in the scientific and regulatory environments.

Other recommendations in the report include broadening staff with the statistical and epidemiologic expertise needed to analyze collected data as well as staff with expertise in risk assessment and its quantitative measurement. A major focus of the report was the need to establish information standards that permit sharing and aggregation of information from public and private postmarketing safety surveillance databases. The report noted that these standards were critical, especially with the establishment of new sciences, including pharmacogenetics, nanotechnology, and cell-based products, for which collection of the necessary extent and types of data will not be supported by current systems.

In terms of funding these improvements, the report stated that appropriation provided by PDUFA IV supplied only a small portion of what was needed. The

Science Board called for a 2009 budget to address the identified shortcomings and directed the FDA Commissioner to develop an action plan to implement the report's recommendations. Calls to increase FDA funding are echoed by healthcare professionals, research, and consumer sectors through entities such as the Alliance for a Stronger FDA.[54] The Alliance, whose members include former Secretaries of the Department of Health and Human Services and Commissioners of the FDA, aims to build awareness regarding current deficits in funding and advocate for increased federal appropriations to reduce the FDA's reliance on user fees paid by drug manufacturers.

In 2009, the FDA launched the Safe Use Initiative which functions as a partnership with external public and private stakeholders with the stated goal of reducing preventable harm from medications.[55] This collaborative group identifies specific areas of focus or cases where there is demonstrated harm, and then works with partners to develop and implement interventions to reduce this harm. Since launching, initiative projects have addressed many high-impact issues, such as safety concerns associated with acetaminophen and opioids, as well as the use of atypical antipsychotics in pediatric populations.[56]

Other FDA efforts to enhance drug safety have included improved guidance to industry on premarketing risk assessment, development and use of risk-minimization action plans, and pharmacovigilance and pharmacoepidemiologic assessment.[57-59] Consumer awareness and education has also been a major focus, including new regulations that require inclusion of MedWatch reporting information on drug packaging and patient information leaflets for prescription and nonprescription drugs and in direct-to-consumer television advertising.[60-62]

IMPROVING DATA COLLECTION AND USE

At the core of efforts to improve drug safety, there is reliance on the extent and quality of information used to inform these decisions. Safety information gained from premarketing as well as postmarketing studies is often described as data that are unreported, underreported, and unpublished. The International Committee of Medical Journal Editors Uniform Requirements for Manuscripts Submitted to Biomedical Journals requirement that researchers register human subjects research on the website www.clincialtrials.gov as a condition of publication and the editor's obligation to publish negative studies represent the combined efforts of regulatory and private entities to address these shortcomings.[63]

Other efforts have focused on developing standards for reporting drug-induced diseases and other adverse drug events. The Consolidated Standards of Reporting Trials (CONSORT), in "Better Reporting of Harms in Randomized Trials: An Extension of the CONSORT Statement," recommends the use of standardized terminology and inclusion of harms information in the publication abstract as mechanisms to assist clinicians, researchers, and patients in the critical appraisal of clinical trial results.[64] Public and private collaborations to improve active surveillance, including data mining in large population-based databases, are described in Chapter 4.

DRUG SAFETY CHALLENGES AND OPPORTUNITIES

As noted in the FDA Science Board report, the rapid rate of new drug development, the evolving role of evidence-based medicine, and advancing science and technology offer ongoing and new challenges to our nation’s drug safety system. Novel first-in-class drugs, nanotechnology, cell-based therapies, large-molecule biologics, and biosimilars are among many challenges in assessing and ensuring postmarketing drug safety.

Pharmacogenomics and personalized drug therapy have the potential to improve the prediction and prevention of drug-induced disease from the perspective of both individual patients and entire populations. One of the earliest known genetic variations to result in drug-induced disease is glucose-6-phosphate dehydrogenase deficiency, which results in the destruction of red blood cells when a person is exposed to certain drugs (e.g., antimalarial agents, aspirin, nonsteroidal anti-inflammatory drugs, quinidine, quinine, and sulfonamide antibiotics). More recent discoveries include variations in the organic anion transporter *SLCO1B1*, which are associated with an increased risk of statin-induced myopathy.[65]

Many factors contribute to genetic variation in response to drug therapy. Polymorphisms, which can be affected by the interplay of more than one genetic variation, may lead to differences in drug disposition, including absorption, distribution, and excretion.[66] These differences can lead to decreased or increased pharmacologic effect, with the latter more frequently resulting in toxicity or undesired drug effects. Genetic differences in drug transporters also play a role in response to drug therapies. Examples of drugs, genetic variables, and the proposed associated adverse drug event are described in Table 1-3.[66,67]

Some genetic polymorphisms are more common in certain racial groups; therefore, ethnicity has been used to predict drug response in the absence of more specific genetic information for an individual patient.[68] For example, the relative risk of angioedema or cough associated with the use of angiotensin-converting enzyme (ACE) inhibitors has been estimated at 3 and 2.7 for blacks and East Asians, respectively, as compared with whites. Other studies, including the Gruppo Italiano per lo Studio della Sopravvivenza nell’Infarto Miocardico (GISSI)-1 trial found that intracranial hemorrhage or moderate-to-severe bleeding following thrombolytic therapy was more common in black patients.[24,69] Although these and other studies give credence to ethnicity as a determinant of adverse events, shortcomings in the data, including inconsistent definitions and reporting of ethnicity and adverse events, limit its application to clinical practice. Most drug-induced diseases, including ACE-inhibitor–induced cough, have been theorized as a complex interaction of ethnic and other factors such as age, sex, and comorbid disease.[70] When considered in total, these predictive factors can be used to improve drug safety by guiding drug selection and monitoring.

Table 1-3 Examples of Drug-Induced Diseases Associated with Genetic Variability[66,67]

Drug	Genetic Variation	Adverse Drug Event or Drug-Induced Disease
Abacavir	*HLA*	Hypersensitivity reaction
ACE inhibitors	Bradykinin B_2 receptor	ACE inhibitor-induced cough and angioedema
Carbamazepine	*HLA-B*1502* allele	Stevens–Johnson syndrome, toxic epidermal necrolysis
Cisplatin, carboplatin, and oxaliplatin	Changes in gene expression in the dorsal-root ganglia resulting in apoptosis (*Cdkn1a, Ckap2, Bid3, S100a8, S100a9*), inflammation (*S100a8, S100a9, Cd163, Mmp9*), and nerve growth and regeneration (*Mmp9, Gfap*)	Peripheral neurotoxicity
Digoxin	P glycoprotein *3435TT* genotype	Increased drug accumulation and potential for digoxin toxicity
Mercaptopurine	Thiopurine methyltransferase polymorphism	Hematopoietic toxicity
Oral contraceptives	Variation in prothrombin and factor V	Increased risk of DVT or cerebral vascular thrombosis
Trimethoprim–sulfamethoxazole, clarithromycin, quinidine	*KCNE2* variants in potassium channels	QT interval prolongation, morbidity, and mortality

ACE = angiotensin-converting enzyme, DVT = deep vein thrombosis, HLA = human leukocyte antigen.

The inclusion of genetic biomarker information and its clinical application in FDA-approved drug labeling is becoming more common. In 2013, the FDA issued guidance to assist manufacturers in applying pharmacogenomics in premarket clinical studies and in labeling decisions.[71] An evaluation of ten drugs previously withdrawn from the market determined that the severe adverse effects that led to this action could all be attributed to genetic variation.[72] The authors concluded that with proper patient selection and monitoring these drugs could have remained on the market. Despite the promise of pharmacogenomics, currently there is no requirement that pharmaceutical manufacturers complete genetic studies. Further, whether these studies are voluntary or required, more research (including practical clinical trials) and better systems for collecting and analyzing these data are needed. Even with improved data, uncertainties will remain regarding the extent to which genetics affects drug response and the interplay of genetics with other variables, including concomitant therapies, diet, and other patient variables. At present, the clinical significance of genetic variation and genetic testing in drug safety and effectiveness are much debated.

As the regulatory and legal environments evolve, clinicians will continue to play a central role in improving drug safety and preventing drug-induced disease. The identification and management of adverse effects, participation in spontaneous reporting efforts, and provision of patient education that addresses both the risk and benefit of therapies are critical and core clinician responsibilities. As illustrated by the example of thalidomide, drugs with significant safety concerns can provide great health benefits when properly managed. Medication-therapy management and other care provided by pharmacists are essential components of the drug safety system.

Note: The authors wish to acknowledge the work of Dr. Nayahmka McGriff-Lee, who authored this chapter in a previous edition.

CHAPTER 2

Epidemiology and Public Health Impact of Drug-Induced Diseases

John R. Litaker and James P. Wilson

Medications are an essential component of modern healthcare. Individuals take medications to feel better, overcome illnesses, treat infections, and improve quality of life. Currently, there are thousands of drugs and drug products approved by the U.S. Food and Drug Administration (FDA) available on the American market.[1] Therapeutic benefits associated with prescription and nonprescription medications often imply safety and calculated risks to the general public. However, despite the healing benefits of medications, risks remain that can lead to adverse events and drug-induced diseases. In the seminal report *Preventing Medication Errors* in 2006 the Institute of Medicine acknowledged the seriousness of adverse drug events in hospitals by noting that "[medication] errors are common during all steps of the medication-use process—[from] procuring the drug, prescribing, dispensing, administering, and monitoring the patient's response."[2]

Public assumptions of drug safety may be partially attributable to the FDA's approval and regulatory process. Drugs undergo a rigorous testing and clinical trial process prior to approval to ensure safety and efficacy. Yet some people, including healthcare practitioners, may assume that FDA approval implies absolute safety, despite the fact that there are risks associated with using any medication. Even the FDA recognizes that every approved drug carries some risk and that “for every drug [the] FDA approves, the benefits are balanced against [these] risks.”[3] These adverse drug events may be mild or severe depending on the particular product, expected dose, or patient population, and may subsequently manifest as a drug-induced disease.

Medication errors are one cause of drug-induced diseases. In 2000, the Institute of Medicine reported the extent and impact of errors in healthcare in its publication *To Err Is Human*.[4] This report noted that medication errors were “one of the most common types of error” and that substantial numbers of people were affected.[4] Other sources of drug-induced diseases are related to the pharmacologic characteristics of the product itself and do not necessarily involve dispensing or dose errors. Pharmacists and physicians should be keenly aware of the known potential adverse events associated with each drug, because these events are detailed in the product’s safety insert. Even well-known products such as aspirin are associated with serious adverse events. Indeed, speculation abounds that aspirin would not meet today’s FDA risk-benefit balance because of serious adverse events such as gastrointestinal bleeding.[5]

This chapter focuses on the epidemiology of drug-induced diseases and the impact on both the public’s health and the healthcare system. The cost of drug-induced diseases to the healthcare system is also discussed.

OVERVIEW OF EPIDEMIOLOGY

Epidemiology has its historical roots dating back to the philosopher Hippocrates, who, as early as the 4th century B.C., recognized the relationship between disease and environmental, temporal, and geographical factors.[6,7] In more recent times, epidemiology gained considerable attention when John Snow, a physician and epidemiologist, used epidemiologic techniques to identify the source of cholera epidemics in London in the mid-1850s. He mapped the location of each cholera case and noted an association between its geographic location and the company that supplied water to that location. Morbidity and mortality were highest among people who received water from the Southward Company. Further research determined that cholera was spread by contaminated water from this company.

In *A Dictionary of Epidemiology,* John Last defines epidemiology as the “study of the occurrence of disease or other health-related characteristics in human populations,”[8] while Jekel et al.[9] define it as “the study of factors that determine the occurrence and distribution of disease in a population.” More specific to drug-induced diseases is the term *pharmacoepidemiology*, which is defined as “the study of the distribution and determinants of drug-related events in populations and the application of this study to efficacious drug treatment.”[10] Common to all three definitions is the idea of disease distribution (or diffusion) and disease determinants (or causal factors). Indeed, determining why and how diseases spread from place to place is the essence of epidemiology.

Determining the epidemiology of drug-induced diseases and their impact on the public's health requires a sound methodologic system to establish: (1) the frequency of drug-induced diseases; (2) nonmedical factors contributing to drug-induced diseases; (3) particular medications, doses, and routes of administration associated with drug-induced diseases; (4) the temporal and geographic distribution of drug-induced diseases; and (5) specific patient characteristics associated with drug-induced diseases. Epidemiology and its specific tools are extremely useful and important in understanding drug-induced diseases. Epidemiology provides a scientific and rigorous approach toward answering specific questions and can be used to identify associations, provide strength of evidence, and establish causality. A variety of epidemiologic techniques and research methods are available, including ecologic studies, cohort studies, cross-sectional studies, case–control studies, and randomized, controlled trials. The reader is advised to consult an epidemiology textbook for more detailed explanations of these and other study methods.

LEVELS OF EVIDENCE

Levels of evidence are used to stratify epidemiologic tools according to the strength of influence that these studies may contribute to the decision-making process. The basis for this strength of influence is the study design itself. For example, an experimental-design study will naturally have more influence than a nonexperimental-design study. **Table 2-1** identifies the three levels of evidence, with the associated study type, that are used throughout this book.

However, the reader is cautioned not to rely on the randomized clinical trial as the sole factor in the decision-making process. Each study type has a specific role to play in decision-making, but this role is limited to the type of evidence that the study can provide. In addition, emerging outcomes (whether it is a disease or an adverse drug event) may not readily appear as a problem in its early stages. In such instances, case reports may be the only source of evidence that such a problem is occurring. A prime example of this is a retrospective review of case reports from the mid-1950s of individuals in Africa, North America, Western Europe, and the Middle East reportedly dying of what was then called a "wasting disease."[11] At the time that the case reports were compiled, blood samples were obtained from the dying individuals and stored. Three decades later, researchers tested these blood samples and found that these individuals were infected with the human immunodeficiency virus.

Table 2-1 Levels of Evidence for Drug-Induced Diseases Used in This Book

Level of Evidence	Source of Evidence
A	One or more randomized, controlled clinical trial
B	Nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case–control studies, meta-analyses, and/or postmarketing surveillance studies
C	Evidence from one or more published case reports or case series

OVERVIEW OF PUBLIC HEALTH

Public health is concerned with the programs, services, and institutions involved with preventing disease, meeting the health needs of the population, and emphasizing the proper distribution, allocation, and access to health services for all citizens. In England, public health has been defined as "the science and art of preventing disease, prolonging life, and promoting health through organized efforts of society."[12] Public health officials use epidemiology as a tool to help with risk factor analysis, evidence-based policy-setting, and decision analysis.

In addition to epidemiology, biostatistical analyses are used to help public health officials determine the probability and causal relations between drug use and an adverse event. Indeed, biostatistics can help determine at the most basic level whether an occurrence is due to chance alone or to an association with a drug. For example, during the past 10–15 years there has been substantial controversy regarding the administration of the measles, mumps, and rubella (MMR) vaccine in the United Kingdom and the possible link of the vaccination to autism. Biostatistics and epidemiology have been used to determine whether autism is more or less likely to occur in vaccinated children as compared with the general population. The basic premise is that if autism is more likely to develop in vaccinated children (as determined statistically) than in children in the general population, then the association should be further explored to determine whether causality exists. That is, does the vaccine cause autism? Or is there some unaccounted factor that also occurs, but is unrecognized, that causes autism in vaccinated children? Epidemiologic investigations have concluded that there is no evidence linking the MMR vaccination to autism, thus highlighting the importance of epidemiology.[13]

EPIDEMIOLOGY OF DRUG-INDUCED DISEASES

Epidemiology is important in the study of drug-induced diseases. Among other things, epidemiology as applied to pharmaceuticals can be used to investigate the therapeutic effects, risks, and use of drugs in society. Epidemiology is often used to help explain morbidity and mortality questions associated with particular medications. In August 2003, epidemiologists from the U.S. Department of Defense were asked to determine whether there was a causal relationship between the antimalarial drug mefloquine and unexplained domestic killings among recently returned soldiers from Afghanistan.[14] No causal link between mefloquine and the violence was established.

A key obstacle in identifying the cause of drug-induced diseases is recognizing the reaction as a drug-induced disease and distinguishing it from spontaneous (i.e., occurring without taking the drug), yet similar, clinical manifestations that are not drug-related.[15] Another obstacle is determining the numerator (i.e., number of patients with a drug-induced disease) and denominator (i.e., population who took the drug) necessary to calculate the morbidity or mortality rate associated with a particular medication.

In attempting to determine causality of a potential drug-induced disease by a particular agent, it is important to remember that association does not imply causation. Simply put, this means that although a reaction may appear to occur in tandem with a particular drug, it does not necessarily imply that the drug caused the reaction. Indeed, the importance of determining causality was outlined by Professor Sir Austin Bradford Hill, from the London School of Hygiene and Tropical Medicine, in 1965. In particular, Hill stated: "Our observations reveal an association between two variables, perfectly clear-cut and beyond what we would care to attribute to the play of chance. What aspects of that association should we especially consider before deciding that the most likely interpretation of it is causation?"[16] Hill suggested that the following aspects should be considered before causality can be determined, and these are presented with a specific emphasis on drug-induced diseases:

- *Strength of association*—Is there a strong association between a suspected drug-induced disease in people taking the drug versus those not taking the drug? If the association is strong (e.g., a relative risk >3), then one would be more confident that a causal effect exists. An example is the strength of association between pregnant women taking thalidomide and giving birth to a disfigured child. Indeed, this association was so strong that thalidomide was withdrawn from the German market in November 1961 and was not commercially available again until the United States, in July 1998, introduced it to treat erythema nodosum leprosum, but with specific safeguards to prevent it from being used by pregnant women.[17]
- *Consistency*—Does the suspected drug-induced disease occur repeatedly in different persons, at different times, and in different places? Indeed,

consistency is a hallmark feature that must occur before causality can even be suggested.

- *Specificity*—Is the suspected drug-induced disease specific to that drug? For example, individuals who take excessive doses of digitalis for heart failure often see “halos.” When they stop taking the drug and the plasma digitalis concentrations decrease, the halo effect disappears. Could there be other causes for these patients seeing halos or is it likely only due to digitalis overdose?
- *Temporality*—Does the suspected drug-induced disease manifest before or after drug exposure? To even consider causality, the person must be exposed to the drug before the occurrence of the adverse outcome. If the person is not exposed to the drug before the drug-induced disease occurs, then causality cannot be considered.
- *Biologic gradient*—Does the incidence of the suspected drug-induced disease increase when higher doses of the drug are taken? For example, can we detect increased toxicity with increased doses of a particular drug (e.g., acetaminophen and liver toxicity)?
- *Plausibility*—Is the suspected causation plausible? That is, if a particular adverse event occurs after administration of a particular drug, is it biologically (pharmacologically and physiologically) plausible that the drug caused the event or was it merely coincidental?
- *Coherence*—Does the suspected causation conflict with or support that which is generally known about the disease and its progressive pathology?
- *Experiment*—Is it possible to manipulate the degree of exposure to prevent or enhance the outcome? For example, if a particular drug is suspected of causing a rash in a patient, does the rash disappear after discontinuing the medication, and does subsequent rechallenge cause the rash to reappear? (Note that rechallenge is rarely desirable or ethically appropriate in a clinical setting.)
- *Analogy*—Can the previous experience with a particular medication causing a drug-induced disease be used to enhance our ability to detect or accept a similar outcome with a different drug under similar circumstances? For example, because of the thalidomide debacle of the 1960s, we now know that it is within the realm of possibility that a drug taken during pregnancy can cause birth defects.[17]

In addition to the Hill criteria, Naranjo et al.[18] proposed a method for estimating the probability of adverse reactions. This method uses a probability scale to determine “causality of [adverse drug reactions] in a variety of clinical situations.”[19] Although the term *causality* should be replaced with *correlation,* the proposed method is shown to have high between-rater and within-rater reliability on both initial testing and retesting. Clinicians may wish to use this scale as a tool to assess correlation between a medication and an adverse drug event.

CATEGORIZATION OF DRUG-INDUCED ADVERSE EVENTS

Once association between a drug and an adverse event is determined, it is useful to classify the adverse event. Four categories have been suggested to aid in the proper management of any iatrogenic illness[15]:

1. Conscious risk
2. Unexpected complications
3. Inept care
4. Overzealous care

Conscious risk and unexpected complications represent adverse events due to "balanced, informed consideration of benefits and risks."[16] In essence, these two types of drug-induced adverse events are part of the normal risk–benefit consideration inherent when prescribing any drug for any condition to any person. That is, there is always the potential for unintended or unpredictable drug effects on the body. However, both conscious risk and unexpected complications can be mitigated by knowing the risk factors associated with the drug-induced disease, assessing patients for these risk factors, providing optimal doses, and identifying other therapeutic interventions.[16] The latter two categories represent errors of omission and errors of commission, respectively, and represent inappropriate medication use due to a lack of understanding or education about the drug and its impact in the patient for whom it is prescribed.[16]

QUANTIFYING THE IMPACT OF DRUG-INDUCED EVENTS

Determining the quantitative impact of a drug-induced disease to society requires the use of a rigorous and fact-based epidemiologic approach. Several methods for quantifying the impact have been developed, with the simplest being the attributable risk percent measure reported by Cole and MacMahon in 1971.[19] This simple approach relies on the odds ratio (OR) and is expressed as the following:

$$p = (\mathrm{OR} - 1)/\mathrm{OR}$$

where p is the probability that the symptom is the result of taking the drug, and OR is the ratio of the odds of exposure among the cases to the odds of exposure among the controls and is usually accompanied by a 95% confidence interval (CI) to aid in the interpretation of statistical significance.

An example is to determine the quantitative impact of a drug-induced disease of two alternative therapies for the same condition. In 2004, the safety and tolerability of two aerosolized antifungal prophylaxis medications in lung transplant recipients were assessed. Subjects receiving amphotericin B deoxycholate were more likely to have experienced an adverse event than subjects receiving amphotericin B lipid complex (OR 2.16, 95% CI 1.10–4.24, $p = 0.02$).[20] Using the equation above, the quantitative impact of adverse events due to amphotericin B deoxycholate is the following:

$$p = (2.16 - 1)/2.16 = 53.7\%$$

However, additional criteria (e.g., Hill’s causality criteria) must also be considered before making a definitive judgment regarding causality.

TRENDS IN REPORTING DRUG-INDUCED EVENTS

The FDA manages the Adverse Event Reporting System (AERS) database, which is a repository of adverse event and medication error reports submitted to the FDA and “serves as a postmarketing safety surveillance program for drug and therapeutic biologic products.”[21] Although data and results emanating from AERS should be interpreted with some caution due to limitations inherent in a self-reporting system, the AERS database provides useful information on trends related to the impact of adverse drug events generally and on trends related to new drugs or new drug classes specifically. The nonprofit Institute for Safe Medication Practices monitors and reports on data collected by AERS.

In 2015, the most recent year in which complete data are available, the FDA, through AERS, collected just over 1.16 million reports of adverse drug events.[22] This represents a 32.9% increase from the preceding year. Although the overall increase in number of reports from 2014 to 2015 is substantial, much of this variance can be ascribed to information technology improvements related to how information is reported and regulatory changes that reclassified lower-priority reports into the AERS system.[22] As such, the number of nonserious events increased by 73.2% from 2014 (n = 328,929) to 2015 (n = 569,760) while the number of serious events increased by 9.9% from 2014 (n = 298,979) to 2015 (n = 328,524).[22]

For the domestic serious event category some interesting trends were identified in 2015 data. These include an overall increase in serious adverse drug event reports, a high number of reports for a new class of oral diabetes drugs (the sodium-glucose cotransporter-2 [SGLT2] inhibitors), and the ability to identify drug-associated risks in the post marketing phase of the drug development process.[22] For example, approximately 20% of adults 65 years of age and older are now taking medication to lower their blood glucose concentrations. In the fourth quarter of 2015, over 2 million prescriptions were written for the SGLT2 inhibitors, which promote excretion, rather than reabsorption, of blood glucose and sodium—a nearly sixfold increase from the first quarter of 2014.[22]

The increase in number of prescriptions for a new class of drugs is not in and of itself problematic. Rather the issue is the ability to extrapolate medication safety data to the public at large based on clinical trial data, which are collected from limited and controlled populations. As such, phase IV studies offer postmarketing surveillance to assess "the real world effectiveness of a drug as evaluated in an observational, non-interventional trial in a naturalistic setting which complements the efficacy data that emanates from a pre-marketing randomized controlled trial."[23] In the case of SGLT2 inhibitors, time will ultimately provide evidence on the risk-benefit analysis. However, from current data, there is "evidence [that] multiple safety problems has emerged."[22] From an epidemiology and public health perspective, there is a need to monitor the real impact of new medications in the population. Using the AERS database can support this effort.

PUBLIC HEALTH IMPACT OF DRUG-INDUCED DISEASES

Drug-induced diseases exert a considerable impact on society. They are costly, result in considerable morbidity, and may result in death. Some adverse drug effects are not clinically significant, yet "most [would] agree that any condition that results in hospitalization is significant."[24] In this book, a drug-induced disease is defined as an unintended effect of a drug that may result in mortality or morbidity or cause symptoms sufficient to prompt a patient to seek medical attention and/or require hospitalization. Costs associated with drug-induced diseases have considerable implications for public health policy and planning. For example, costs associated with drug-induced diseases not only divert healthcare resources but also have measurable (e.g., hospitalization) and societal (e.g., lost time from work) costs. From a clinical standpoint, prevention of drug-induced diseases is preferable to treatment after the fact. Fortunately, many drug-induced diseases are preventable. This section explores issues related to the public health implication of drug-induced diseases.

DETERMINING THE INCIDENCE OF DRUG-INDUCED DISEASE

Determining the incidence of drug-induced diseases can be a daunting task, chiefly because it is difficult to determine the associated numerator and denominator. The numerator is defined as the number of new drug-induced disease events occurring during a defined period, while the denominator is defined as the population at risk for the drug-induced disease during the same period. In the general population, the denominator is the number of people exposed to a particular medication and may be identified by using computerized prescription data or medical records. In reality, however, numerous obstacles exist in determining the denominator, because it is difficult to identify the population of interest and to determine how many people in this population have been exposed to the drug. Determining the numerator is also difficult because there is no systematic method of assessing the occurrence of drug-induced diseases in individuals unless the occurrence is serious enough to warrant further medical attention.[24]

Data from hospital admission studies can be used as an appropriate measure of drug-induced disease incidence because (1) medical record data can be used to determine potential association, and perhaps causation, between a particular drug and disease; and (2) drug-induced events precipitating hospitalization are deemed serious enough to be clinically significant and thus would seem to represent a higher burden to society. Indeed, Nelson and Talbert note that “the rate of drug-related admissions is a measure of a subset of the clinically significant related morbidity. Determining this rate could identify some of the cases of drug-related morbidity.”[24]

Another obstacle in determining the incidence of drug-induced diseases is that, in many cases, medications are not recognized as the cause of the symptom or disease. Therefore, a particular drug may not be recorded or reported as a potential cause. Clinicians may be slow in recognizing a drug-induced disease because not all adverse events are reported in the literature or necessarily known to the FDA at the time of approval. For rare events (e.g., a drug-induced disease occurring in 1 of every 10,000 people), the likelihood of detection before approval and widespread use is low because the clinical trial process, although rigorous, is not designed to identify all drug-related adverse events. It is often only after a drug reaches the market and is used by a much larger patient population that rare events are identified. Therefore, the importance of postmarketing surveillance activities and signal-detection activities cannot be overstated.

DRUG-RELATED HOSPITAL ADMISSIONS

As noted earlier, drug-induced hospital admissions are a sign of serious clinical events. Sometimes these admissions are avoidable, and other times they are not.

For example, a patient with a known allergy to penicillin who is subsequently prescribed this drug and develops anaphylactic shock represents a case of an avoidable hospital admission. On the other hand, a patient may receive a medication that causes a drug–drug, drug–food, or drug–laboratory interaction with subsequent hospitalization that is unavoidable because these interactions were previously undescribed, were previously unknown, or were idiosyncratic in nature.

In a 1993 review, the incidence of drug-related hospital admissions was reported to range from 0.2% to 21.7%, with a median rate of drug-related hospitalizations of 4.9%.[25] The author defined drug-related hospitalizations as adverse events that could cause a side effect, excessive effect, idiosyncratic effect, or hypersensitivity. All of the reviewed studies were conducted in large hospitals, with most located in urban areas. Sample sizes (or total admission numbers) ranged from 41 to 11,891, with a total patient population size of 69,187. Only nine of these studies reported incidence rates above 7%, representing just 6.3% of the patient population assessed (4,420/69,187). The highest reported incidence of 21.7% occurred in a teaching hospital with oncology patients as the predominant population. The primary implicated medications for drug-related admissions in this group were theophylline, cancer chemotherapy agents, and trimethoprim–sulfamethoxazole. In another review, covering the period from 1959 through 1992, 0.3–16.8% (median 5.6%) of all hospital admissions were drug-related.[15]

Determining the rate of drug-induced hospital admissions is dependent on the study population, the ability to extract sufficient medical information, and the study method. Most studies of drug-related admissions rely on a medical record review by a clinical pharmacist. Such a review typically defines a drug-induced admission and establishes criteria for objectively determining whether an admission meets that definition. The definition of *drug-related admission* can include an adverse drug reaction, dose-related therapeutic failures, improperly treated conditions, and drug interactions. Among studies assessing drug-related admissions, wide-ranging results are possible due to variation in prescribing patterns, differences in patient populations, and differences in defining drug-induced illness.

The true extent of drug-related hospital admissions remains a mystery, because it is not possible to make a collective determination of the overall prevalence based on a collection of disparate studies. As Manasse pointed out, although published reports provided useful information about drug misadventuring, these reports were extremely limited "in establishing a national mortality, morbidity, or incidence rate."[26] However, these studies can provide some information about drug-related hospital admissions. For example, reports can inform us about the types of drugs and drug classes frequently implicated in drug-related hospital admissions and potential causes of drug-related problems (e.g., drug–drug interaction, nonadherence, etc.). As an example, in a study published in 2011, researchers in the Netherlands identified the most common reasons for a potentially preventable drug-induced hospital admission as gastrointestinal problems (15%), cardiovascular symptoms (11%), respiratory symptoms (8%), and issues with glycemic control (6%).[27] Reports also can inform us regarding the reason for a medication error. For example, a 2013 report noted drug errors were caused by errors in ordering and prescribing (53%), receiving or administration (13%), monitoring or follow-up (13%), implementing or dispensing (10%), documentation (7%), and others (4%).[28]

Many studies have identified drug types and drug classes frequently implicated in drug-induced hospital admissions. Although the results of these studies vary in terms of drug classes implicated and the number of adverse events associated with each drug class, some general trends are noted. For example, cardiovascular drugs are often implicated in drug-induced hospital admissions. Chiefly among this group are digitalis, diuretics, and angiotensin-converting enzyme inhibitors. See **Table 2-2** for a list of drug classes commonly associated with drug-induced hospital admissions.

Table 2-2 Drug Classes Commonly Associated with Drug-Related Hospital Admissions

- Antidiabetics/hypoglycemics
- Cardiovascular drugs (e.g., ACE inhibitors, diuretics, digoxin)
- Psychotropics
- Gastrointestinal drugs
- NSAIDs
- Anticonvulsants
- Antineoplastics
- Corticosteroids
- Antibiotics

ACE = angiotensin-converting enzyme, NSAID = nonsteroidal anti-inflammatory drug.

COSTS

Costs associated with drug-induced diseases can be quite substantial. Unfortunately, most approaches used to assess the economic impact of a drug-induced disease have methodological limitations that require numerous assumptions, make it difficult to quantify the number and types of medication errors that occur, are often focused on a particular setting, and may lack accurate cost information with which to conduct economic analyses. Additional issues include determining causality and difficulty in properly identifying the numerator and denominator.

Nevertheless, the literature is replete with studies seeking to address the cost burden of drug-induced diseases. A review of the literature from 2010 forward indicates varying assessment methodologies are used with wide ranges in costs purported to be associated with drug-induced diseases. For example, a study in 2011 from The Netherlands reported an average cost for a preventable drug-induced medication-related hospitalization of €5,461[27] while a study in 2015 from Germany reported an average cost for a preventable drug-induced related hospitalization of €2,743.[29]

As with the two studies noted above, findings from articles reporting on the cost burden of drug-induced diseases since the late 1990s are based on a wide range of methodologies, assumptions, and sources of information—all of which are associated with limitations. Samp et al. point out the following:

> Currently published studies on cost of medication errors have many additional limitations. Because of the difficulty in quantifying all types of medication errors, most studies focused on a specific healthcare setting. In addition, many studies examined only errors that were documented in patients' medical records or those errors that resulted in patient harm. Although this information may be more easily available, this type of limited analysis leads to a gross underestimation of the true rate of medication errors and a potential overestimate of medication error costs.[30]

For example, researchers reported on the monetary costs associated with hospitalization due to drug-induced diseases in Australia over an 8-year period from 1988 to 1996.[31] In this study, investigators simply calculated a mean average cost based on average length of stay and average daily cost of hospital care. The report did not include costs of outpatient visits, return visits to a physician's office, pharmacy costs, or additional treatment costs. **Table 2-3** describes items that should be included in a comprehensive health economic assessment.

Table 2-3 Costs to Consider When Conducting a Health Economic Evaluation

Direct medical costs

- Hospitalization
- Outpatient service (including ancillary services)
- Pharmacy costs
- Diagnostic procedures and tests (e.g., laboratory tests, electrocardiography, chest radiography)
- Surgery
- Extended nursing or home health costs
- Follow-up care (e.g., return visits to the hospital or primary care physician and additional ancillary services such as radiology or laboratory testing)

Direct nonmedical costs

- Transportation to and from the medical provider

- Services (e.g., Meals on Wheels and social assistance)
- Adopting devices and instruments

Indirect costs

- Sick leave
- Reduced productivity
- Early retirement
- Premature death

In 1995, researchers at the Center for Pharmaceutical Economics at the University of Arizona developed a comprehensive cost-of-illness approach associated with drug-related morbidity and mortality based on a probability pathway model.[32] In this model, costs were determined based on specific outcomes associated with treatment. When a patient receives drug therapy, four possible outcomes are possible: (1) optimal therapeutic outcome, in which the patient recovers from the illness; (2) treatment failure; (3) a new medical problem; and (4) a combination of treatment failure and a new medical problem. Therefore, this model went beyond addressing drug-induced diseases, and included drug-related events including treatment failures. It stands to reason that attaining an optimal therapeutic outcome is the desired end result. For patients who do not reach this outcome, additional scenarios are possible: no further treatment, an additional physician visit, additional treatment, an emergency department visit, hospitalization, long-term care admission, or death.

Based on this cost-of-illness model, total estimated morbidity and mortality costs for drug-related diseases were $76.6 billion in 1995.[32] A follow-up study in 2001, using the same cost-of-illness model, reported annual drug-related morbidity and mortality costs (in year 2000 dollars) of $177.4 billion.[33] By comparison, the cost of cardiovascular diseases and stroke were estimated to be $316.6 billion in 2011–2012, and the cost for all cancers during this period was estimated at $88.7 billion.[34]

When these figures are analyzed by cost center, hospitalization was the single highest cost driver for drug-related morbidity and mortality, with 1995 expenditures of $47.4 billion and 2000 expenditures of $121.5 billion. In 1995, for example, hospital admissions represented 62% of the total cost. In the 2001 study, hospital admissions accounted for 69% of the total costs. This increase is most likely due to higher costs associated with hospitalizations or medical inflation rather than an increased incidence of drug-related diseases. Costs associated with new medical problems due to a previously prescribed drug therapy are also expensive. Hospitalization costs associated with a new medical problem were estimated to be $5,504 in 1995[32] and $12,797 in 2000.[33]

However, it should be noted that the expenditures presented in this model are estimates. Indeed, hospitalization expenses from the 1995 study assume that 28.2%

of all hospitalizations are due to drug-related morbidity and mortality.[32] This figure is high and is at odds with reported estimates of drug-related hospital admissions cited earlier in this chapter.[15,31] As previously discussed, Einarson[25] reported an overall incidence of drug-related hospital admissions ranging from 0.2% to 21.7%, with a median value of 4.9%. Hallis[15] reported an incidence of drug-related hospital admissions ranging from 0.3% to 16.8%, with a median value of 5.8%. Johnson and Bootman[32] acknowledge this discrepancy by noting that estimates (such as by Einarson[25]) focused on hospital admissions due to nonadherence or adverse drug reactions. Johnson and Bootman further note that estimates in their model included "negative therapeutic outcomes owing to all types of drug-related problems" and, as such, the estimated numbers of hospital admissions "would be expected to be greater."[32] Despite this explanation, these numbers appear to be high compared with empirical evidence and should be judged cautiously in this light. From a clinical perspective, the rate of drug-related hospitalizations may be more appropriately in line with the median estimates of 4.9% and 5.6% reported by Einarson[25] and Hallis,[15] respectively, because their studies represent wide reviews of the published literature on the subject.

In an attempt to provide a more rigorous and comprehensive approach to estimating the cost burden of drug-induced diseases, Samp et al. reported in 2014 on costs associated with medication errors by using a decision-tree model.[30] Such a model allowed for all logical outcomes to be identified along with the unit cost for each outcome. This approach provided a more robust data collection paradigm that could tie a specific medication error end point to the cost of the error and the number of times the error occurred. Components of the Samp et al. decision tree are summarized in **Table 2-4**.[30]

Table 2-4 Key Components of a Decision Tree Model Used to Assess Potential Outcomes due to Medication Errors[30]

- Is there a medication error?
  - o Does this error reach the patient (yes or no)?
- If the error reaches the patient, is the patient harmed (yes or no)?
  - o Is the harm permanent or temporary?
- If the patient has permanent harm is this in the form of death, hospitalization, or no hospitalization?
- If the patient has temporary harm does the patient require hospitalization, no hospitalization, or prolonged hospitalization?
- Is life-sustaining intervention required?
- If the error does not reach the patient, is communication needed with the patient regarding the error or can be it be remedied without communication?
  - o Is the medication regimen changed (yes or no)?
  - o Is medication monitoring required (yes or no)?
  - o Is treatment referral required (yes or no)?

Results from Samp et al.[30] indicated a total of 779 medication errors were observed over a 14-day period with 57.9% (*n* = 451)* of the errors reaching the patient and 9.3% (*n* = 42)* of those errors leading to patient harm. The remaining 90.3% (*n* = 409)* of errors that reached the patient did not lead to patient harm. For those errors that caused harm, 2.5% (*n* = 1) resulted in permanent harm (in this case death) while 97.5% (*n* = 41)* resulted in temporary harm.

From an economic perspective, medication errors were deemed to cost on average $88.57.[30] For those medication errors that did not reach the patient the average cost was estimated to be $6.92, while those medication errors that reached the patient the average cost was estimated to be $147.96.[30] Medication errors that did not cause harm were estimated to cost $11.85 while those medication errors that caused harm to the patient were estimated to cost $1,473.40.[30] The authors noted that these values are considerably lower than those in other reported cost estimates, likely because previous studies base cost estimates solely on medication errors resulting in harm, whereas the inclusion of minor medication errors that did not reach the patient or errors that did not cause harm (both of which represent the largest variance of medication errors in this study) were included in the Samp analysis.

Data from published studies indicate a wide margin in terms of the cost burden associated with a drug-induced disease. From a practical perspective, each study adds to the literature and to the discussion of both health outcomes and the economic cost of medication errors. Such information also provides an opportunity for patients, clinicians, and healthcare settings to focus on quality and to develop processes that can reduce medication errors (such as fully implementing meaningful use capabilities for electronic medical records).[35] Caution, however, is in order when reviewing such findings. That is, it is important for the reader to approach these studies with an appreciation of the limitations, assumptions, and methodological issues inherent in the study design.

MORTALITY

Mortality due to drug-induced diseases is a major concern for pharmacists, physicians, and other healthcare providers. Mortality associated with drug-induced diseases presents an emotional and economic burden to society, especially in cases for which the cause is preventable. The mean death rate due to adverse drug reactions was reported to be 5% of all hospitalized patients admitted for a drug-related problem.[26] This is over 16 times higher than the mortality rate of 0.3% for all other hospital admissions.[26] In addition, the cost of hospitalization with resultant mortality is one of the most expensive single pathways identified by Johnson and Bootman as a treatment outcome.[32] In 1995, for example, drug-related mortality due to a new medical problem was associated with a total pathway cost of $5,504.[32] In

2001, drug-related mortality due to a new medical problem that resulted in death was associated with a total pathway cost of $12,797.[33]

Finally, it should be noted that although there are morbidity, mortality, and economic costs associated with drug-induced diseases, there are also significant opportunity costs to public health when medications known to be safe and effective are not used. For example, childhood vaccination rates have declined in some cities throughout the United States because of fears of autism. As such, there has been an increase in the incidence of mumps and measles in some communities. This increase in preventable illnesses not only impacts the individual, but also exerts a concomitant effect on the community population, as herd immunity is reduced and individuals not previously susceptible to the illness may become susceptible.

CONCLUSION

Drug-induced diseases are a continuing concern for patients and healthcare practitioners alike. All drugs have the potential to precipitate an adverse event, which, in its most serious form, can lead to a drug-induced disease. Clinical trials and regulatory approval processes are often very good at identifying the most common types of adverse events and the patients in whom they are likely to occur. However, not all drug-induced diseases can be identified *a priori*, no matter how carefully medications are prescribed or regulated. The interplay of drugs with complex physiologic factors renders drug-induced diseases a consideration as part of the risk-benefit profile associated with the administration of any medication.

Epidemiology is useful in assisting clinicians in identifying potential associative or causal influences on diseases induced by a specific drug. At the population level, the examples outlined in this chapter demonstrate the potential for epidemiology to not only identify causal inferences (e.g., thalidomide and birth defects), but to also rule out inappropriate causal inferences (e.g., MMR vaccine and autism). At the patient level, causal inferences may be due to the complexity of the patient’s condition, physiologic responses, and the specific pharmacodynamic interplay associated with a specific medication. The ability to use tools related to association and causation as described by Hill[16] and Naranjo et al.[18] can be useful in identifying potential causal interactions at the patient level.

---

*Samp et al. did not provide individual numbers. Therefore, *n* is calculated (with appropriate rounding) for each individual subpopulation based on the total number of medication errors (*n* = 779) and percentages provided by Samp et al.[30]

CHAPTER 3

Factors Contributing to Drug-Induced Diseases

Tyler Shugg, Abdullah Assiri, and Brian R. Overholser*

Patients can be predisposed to drug-induced diseases by several modifiable and nonmodifiable factors. Nonmodifiable factors include a patient's age, sex, race, pregnancy status, genetics, and comorbid diseases. These factors should be considered when assessing the risk of a drug-induced disease prior to drug administration. Additionally, efforts should be made to minimize or eliminate modifiable risk factors for drug-induced diseases, including cigarette smoking, alcohol and illicit drug use, drug–drug interactions (DDIs), food–drug interactions, medication adherence, and medication errors. This chapter outlines the most important factors that are known to contribute to drug-induced diseases and provides examples of their clinical consequences.

DEMOGRAPHIC FACTORS

AGE

Advancing age is associated with progressive changes in pharmacokinetic parameters, such as reductions in renal and hepatic clearance and an increased volume of distribution of lipophilic medications.[1] Advancing age can also impact pharmacodynamic responses, such as an exaggerated sensitivity to drugs that affect the central nervous system.[1,2] These physiological changes are associated with a greater risk of drug-induced diseases in elderly patients, prompting the development of special guidance, such as the Beers Criteria from the American Geriatrics Society, to appropriately direct medication therapy in this at-risk population.[3,4]

SEX

Based on data from the U.S. Food and Drug Administration's (FDA's) Adverse Event Reporting System, women experience an increased number of adverse drug events, which tend to be more severe than those reported in men.[5] Although the reasons underlying the greater predisposition for adverse drug events in women remain unclear, potential factors include sex-associated differences in prescribing practices, sex-associated differences in pharmacokinetic parameters and pharmacodynamic responses, and the impact of sex hormones on increasing the risk of drug-induced disease.[6-8] As an example, women exhibit a greater risk of the drug-induced arrhythmia torsades de pointes when receiving medications that prolong cardiac repolarization. Torsades de pointes is associated with prolonged QT intervals on the surface electrocardiogram (ECG). The increased risk of this arrhythmia may be mediated by sex hormones, particularly the estrogen to testosterone ratio, which may explain the longer baseline QT intervals in women compared with those in men.[7]

RACE

As technological advances have dramatically improved the understanding of the human genome, pharmacogenetic research has identified genetic factors that influence drug disposition and response. Race, the classification of individuals based on their geographic region of ancestry, is frequently, though somewhat controversially, utilized as an effective marker to predict genotype.[9] Such analyses have identified genetic factors that predispose to drug-induced disease that are more prevalent in specific racial populations.[10] For example, individuals of Han Chinese racial origin have an increased prevalence of the human leukocyte antigen (HLA) variant allele, *HLA-B*1502* (rs3909184G>C and rs2844682G>A), a strong predictor for the development of severe skin reactions, including Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN), associated with administration of carbamazepine.[11-13] Therefore, the probability of carrying certain

HLA variant alleles can be predicted based on a patient's race. Additionally, there are well-known examples of the impact of race on the risk of drug-induced diseases for which the genetic basis has not been elucidated. For example, the mechanism for the increased risk of angioedema upon administration of angiotensin-converting enzyme (ACE) inhibitors in patients of African origin is not well understood but is largely recognized.[12,14,15]

PREGNANCY

Maternity status greatly impacts the risk of drug-induced disease, particularly in the developing fetus. Exposure to teratogenic drugs during the first trimester can significantly impair organ development, while exposure in later trimesters can have detrimental effects on newborn growth, cognition, and organ function.[16] Accordingly, the FDA requires evaluation of the teratogenic potential of medications during drug development and has released guidance to direct medication use during pregnancy.[17]

Pregnancy is also responsible for physiologic changes that alter maternal pharmacokinetics. Pregnancy is commonly associated with decreases in the rate and extent of drug absorption, increases in the volumes of distribution of several medications, increases in the clearance of renally eliminated drugs, and increases in the activity of drug-metabolizing enzymes, such as cytochrome P450 (CYP) 3A4.[18,19] Although these pharmacokinetic changes greatly impact drug exposure, maternity-associated changes most often result in reduced drug action and do not typically predispose mothers to an increased risk of drug-induced disease.[18]

LIFESTYLE FACTORS

CIGARETTE SMOKING

Cigarette smoking is a risk factor contributing to drug-induced disease by altering pharmacokinetic parameters and pharmacodynamic response.[20] Cigarette smoke contains thousands of compounds, many of which are known to contribute to several types of cancer. Polycyclic aromatic hydrocarbons are among the most studied for their mutagenic effect as well as their potent induction of hepatic CYPs 1A1, 1A2, 2B6, and possibly 2E1.[20,21] Several important widely used drugs, including acetaminophen, diazepam, duloxetine, olanzapine, ondansetron, clozapine, and methadone, are CYP1A2 substrates. Smokers generally require higher doses of these drugs compared to nonsmokers. Thus, abrupt smoking cessation can markedly affect the pharmacokinetics of drugs that are CYP1A2 substrates, leading to potentially serious complications.

Cigarette smoking can also impact the pharmacodynamics of drugs, including diazepam, β-adrenergic receptor blockers (β-blockers), hormonal contraceptives, and opioids.[20,22] For example, the risk of adverse cardiovascular events in female smokers greatly increases with the use of oral contraceptives and is even greater in older compared to younger women.[23] Thus, the use of oral contraceptives by women over the age of 35 years who are heavy smokers is contraindicated due to the heightened potential for drug-induced disease.

ALCOHOL CONSUMPTION

Many drugs can interact with alcohol resulting in serious diseases or even death.[24] Alcohol is primarily metabolized in the liver by alcohol dehydrogenase in addition to CYP enzymes including 2E1, 1A2, and 3A4. Alcohol dehydrogenase converts alcohol to a highly reactive and toxic compound, acetaldehyde, which is metabolized rapidly to form acetate and nicotinamide adenine dinucleotide. Acetaldehyde forms protein adducts by binding to enzymes or microtubules, contributing to tissue damage and liver enlargement.[24,25] Therefore, the hepatic metabolism of many drugs may be affected, leading to reductions in efficacy or increased risk of toxicity. Ethanol is also a CYP2E1 substrate that induces its own metabolism. Thus, ethanol is metabolized by CYP2E1 to a greater extent in chronic alcohol users.[24] More importantly, the administration of the CYP2E1 substrate acetaminophen in chronic consumers of alcohol increases formation of the toxic metabolite *N*-acetyl-p-benzoquinone imine (NAPQI), which enhances the risk of hepatotoxicity.[26,27]

ABUSE SUBSTANCES

Cannabis is one of the most commonly used recreational drugs in the world. Cannabis consists of more than 80 cannabinoids that contribute to its effects.[28] One of these constituents is delta-9-tetrahydrocannabinol, which is used clinically to prevent chemotherapy-related nausea and vomiting and to improve appetite in patients with human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS).[29,30] Cannabinoids are highly protein bound, and there is some evidence that they may interact with other highly protein-bound drugs, including warfarin and phenytoin.[31,32] Cannabinoids are also metabolized by CYP2C9 and CYP3A4 and induce CYP1A2 when smoked, similar to cigarettes. Concurrent use of cannabis and CYP1A2 substrates—such as clozapine, olanzapine, haloperidol, and tamoxifen—may necessitate higher doses of these drugs to ensure efficacy.[33] Additionally, patients who are receiving these drugs are at high risk of overdose upon cessation of cannabis because they are likely to be maintained on a higher dose during concomitant cannabis use.

Other widely used illicit drugs include amphetamines and cocaine. Cocaine and amphetamines block the reuptake of monoamines (e.g., dopamine) and inhibit their metabolism. This results in an increased risk of cardiovascular events, hypertensive crisis, and central nervous system adverse events. The risk of these adverse events is enhanced when cocaine or amphetamines are used concurrently with antidepressant drugs, such as selective serotonin reuptake inhibitors and tricyclic antidepressants.[34,35] In addition, amphetamines are metabolized by and inhibit CYP2D6. Concomitant use of drugs that are metabolized by CYP2D6 and amphetamines increases the risk of these drug-induced diseases.[33,35]

COMORBID DISEASES

Comorbid diseases can alter the pharmacokinetics and pharmacodynamics of many drugs and constitute a major cause of drug-induced diseases.[36] Liver and kidney diseases are among the most common disorders that contribute to drug-induced diseases due to decreased drug elimination.

KIDNEY DISEASES

In general, hydrophilic drugs are primarily excreted unchanged through the kidneys.[36] The elimination of these drugs is decreased in patients with kidney diseases due to diminished glomerular filtration and/or tubular secretion. Therefore, patients with kidney disease may be at a higher risk of drug-induced diseases compared to patients with normal kidney function.[37,38] There are several examples of renally eliminated drugs that increase the risk for adverse events, including some β-blockers, nonpotassium-sparing diuretics, insulin, ACE inhibitors, aspirin, warfarin, and clopidogrel.[38]

Kidney diseases may also affect nonrenally excreted drugs by altering absorption, distribution, and clearance. Changes in pharmacokinetics in patients with kidney diseases have been demonstrated for more than 50% of nonrenally excreted drugs approved between 2003 and 2007.[38] The impact of kidney diseases on drug absorption may be a result of gastric pH change, which can alter the bioavailability of certain drugs. Protease inhibitors, immunosuppressants, and erythromycin are examples of drugs with increased bioavailability in patients with chronic kidney diseases.[36,39,40] Proteinuria associated with kidney diseases reduces serum albumin concentrations, which may alter the unbound fractions of highly protein-bound drugs, potentially leading to increased drug effect and toxicity.[41] Hepatic metabolism may also be affected by the marked increase in serum parathyroid hormone concentration that occurs in patients with chronic kidney disease, altering the expression of enzymes involved in phase I and phase II metabolism. Examples of hepatically metabolized drugs for which metabolism is impaired due to kidney disease include midazolam, morphine, and zidovudine.[36]

LIVER DISEASES

The liver is the major organ responsible for drug metabolism. Thus, hepatotoxicity, and in particular liver cirrhosis, can have a substantial impact on drug metabolism and clearance. The extent of impaired drug metabolism is dependent on the severity of injury or disease. Hepatic dysfunction can lead to alterations in absorption, extraction, enterohepatic circulation, and plasma protein binding of hepatically metabolized drugs. There are numerous examples of hepatically metabolized drugs that are associated with an increased risk of drug-induced disease during liver disease, including midazolam, propranolol, morphine, metoprolol, warfarin, and naproxen, among others.[42-45]

OTHER DISEASES

Patients with heart failure, thyroid disease, and electrolyte imbalances are at higher risk of drug-induced diseases due to alterations in the pharmacokinetics or pharmacodynamics of certain drugs. Patients with heart failure with reduced ejection fraction (HFrEF) have decreased cardiac output that results in diminished hepatic blood flow. There is some evidence that a low cardiac output due to HFrEF may result in decreased metabolism of high extraction ratio drugs such as lidocaine.[46] Renal clearance and hepatic blood flow may also be diminished in patients with hypothyroidism. Digoxin and other drugs have been found to provoke exaggerated responses when usual doses are administered to patients with hypothyroidism.[47,48] Additionally, in patients with low serum potassium or magnesium concentrations, there is less competition for digoxin with the Na^+/K^+ ATPase pump, resulting in a higher risk of digoxin-induced arrhythmias.[49]

GENETIC VARIATION

BACKGROUND AND NOMENCLATURE

The overall understanding of the contribution of genetics to drug response has increased in the past decade. Pharmacogenomic studies, including gene candidate and genome-wide scanning approaches, have identified gene variants that increase the risk for drug-related adverse events.[50] The identification of these genetic variants has increased the ability of clinicians to predict drug responses and adverse events that were previously categorized as idiosyncratic adverse drug reactions.[51]

Variability of drug response due to pharmacogenomic factors can be a result of single nucleotide polymorphisms, deletions, insertions, duplications, or any other changes in DNA sequences.[52] Humans are diploid organisms that carry two copies of each gene—one each of maternal and paternal origin— which are referred to as alleles. The variant allele refers to a gene that possesses a genetic mutation while the wild-type allele usually refers to the most common genotype in the population (i.e., nonmutated). The alleles are numbered largely based on the order of discovery with the *1 allele commonly designated as the wild-type. Therefore, a patient that is a carrier of the *1/*1 alleles inherited wild-type alleles for that gene from both their biological mother and father. By having a copy of the same allele from both sources, this patient would be referred to as being homozygous for the wild-type allele. Conversely, a heterozygous patient has two distinct allele copies of the same gene.

The most common variants that alter drug pharmacokinetics and pharmacodynamics and increase the risk for drug-induced diseases are in genes that encode drug-metabolizing enzymes, drug transporters, drug target receptors, or the human leukocyte antigen.[53,54] As more pharmacogenetic tests are developed and translated to the clinic, there is a need to enhance clinician knowledge in the field. The Pharmacogenomics Knowledgebase and the Pharmacogenomics Research Network have established the Clinical Pharmacogenetics Implementation Consortium (CPIC) guidelines to guide clinicians on the use of available tests to enhance pharmacotherapy efficacy and avoid potential adverse drug events.[55] There are several examples of pharmacogenomic tests that are becoming the standard of care in oncology and with drugs like abacavir, carbamazepine, dapsone, and azathioprine.

DRUG METABOLISM

Drug metabolism pathways can be classified into phase I oxidation/reduction or phase II conjugation reactions.[53,54] A majority of the genes that encode for phase I and II enzymes are polymorphic, and mutations in these genes can result in varying clinical phenotypes. Phenotypic variations can range from ultra-rapid metabolizer (UM), normal or extensive metabolizer (NM or EM, respectively), intermediate metabolizer (IM), and poor metabolizer (PM). EMs are commonly homozygous for the wild-type (i.e., *1) alleles whereas PMs are typically homozygous for decreased function alleles. UMs include carriers of gain-of-function alleles that increase metabolism capacity beyond that of EMs. Therefore, if the patient's genotype is known, their phenotype can be predicted. A final important consideration is the activity of the parent drug versus that of metabolites to facilitate prediction of lack of an appropriate therapeutic response or increased risk of an adverse drug event or drug-induced disease.

The CYP enzymes (e.g., CYP2A6, CYP2B6, CYP2C9, CYP2C19, CYP2D6 and CYP3A4) are predominantly responsible for catalyzing phase I drug metabolism reactions. An example of a polymorphically expressed CYP enzyme is CYP2C9. Substrates for CYP2C9 include phenytoin, glipizide, and S-warfarin (active enantiomer). The phenotype for the drug metabolism capacity of CYP2C9 follows those listed in the preceding paragraph; UM, EM, IM, or PM. The phenotype for CYP2C9 can be predicted based on the patient's genotype (alleles present). Patients that carry decreased function alleles, such as the *CYP2C9*2* or *CYP2C9*3* allele, generally require a smaller starting dose of warfarin than wild-type patients when taking into consideration other genetic and clinical factors that influence warfarin dose determination.[56,57] Furthermore, homozygotes for the *CYP2C9*2* (rs1799853C>T) or *CYP2C9*3* (rs1057910A>C) alleles are at a higher risk of serious bleeding events due to decreased elimination of the active warfarin enantiomer. This example, along with other relevant CYP enzymes and alleles, are summarized in **Table 3-1**.

During phase II metabolism, a small water-soluble chemical entity is conjugated onto the substrate through a covalent bond to enhance renal excretion. Phase II drug metabolism includes glucuronidation, methylation, acetylation, and sulfation conjugation reactions. Most conjugated metabolites are pharmacologically inactive, but there are some examples of active conjugated metabolites such as morphine-6-glucuronide.

Mercaptopurine, a thiopurine drug, is used to treat acute lymphoblastic leukemia or as an immunosuppressant for inflammatory bowel diseases.[58] Mercaptopurine is partially inactivated by an S-methylation reaction via thiopurine S-methyltransferase (TPMT).[54] Several studies have shown that patients with certain genetic variations within the *TPMT* gene (homozygous or heterozygous) have no or low TPMT enzyme activity. Absence of TPMT enzyme activity leads to an increased serum concentration of one of the mercaptopurine active metabolites, 6-thioguanine nucleotide, which may result in severe bone marrow suppression.[59]

Glucuronidation is another important process in Phase II drug metabolism. Irinotecan, a cytotoxic agent, exerts a meaningful uridine 5'-diphospho-glucuronosyltransferase (UGT) effect on drug clearance and drug-related toxicity.[60] The active metabolite of irinotecan is SN-38, the elimination of which is facilitated by glucuronidation through the UGT1A1 enzyme. Patients with Gilbert syndrome are homozygotes for the reduced activity UGT1A1 allele (*UGT1A1*28*, rs34815109) and are predisposed to life threatening myelosuppression. These examples are summarized in Table 3-1.

Table 3-1 Examples of Genetic Variations Leading to Drug-Induced Diseases

Gene	Example Drug	Alleles of Interest	Response	CPIC Guidelines Recommendation
METABOLIZING ENZYMES				
CYP2C9[117,118]	Warfarin	Presence of at least one allele of _CYP2C*2_ or _CYP2C*3_	Increase risk of bleeding	Monitor INR more frequently, and adjust dose accordingly
	Phenytoin	Homozygous variants: presence of two decreased function alleles including _*2/*2, *2/*3, or *3/*3_	Increase risk of SJS and TEN	Dose adjustment is recommended
CYP2C19[119]	Clopidogrel	Presence of _CYP2C19*17_ allele	Increase risk of bleeding	Dose adjustment is recommended
CYP2D6[120]	Codeine	Ultra-metabolizer: presence of more than 2 functional alleles	Increase risk of death in children and respiratory depression	Consider alternative therapy
Thiopurine methyltransferase[58,59,121]	Azathioprine and mercaptopurine	Homozygote variant leading to low or deficient activity	Myelotoxicity	Consider alternative therapy, or start with very low dose
UGT1A1[122]	Irinotecan	Homozygous of _UGT1A1*28_ haplotypes	Myelotoxicity	Dose adjustment is recommended
_N_-acetyl transferase[123,124]	Isoniazid	n/a	Increase risk of lupus syndrome	n/a
	Hydralazine	n/a	Increase risk of hepatotoxicity	n/a
DRUG TRANSPORTERS				
SLCO1B1[125]	Statins (simvastatin)	Presence of at least one alleles of _SLCO1B1*5_ _SLCO1B1*15_ _SLCO1B1*17_	Myopathy Rhabdomyolysis	Consider starting with lower doses or an alternative agent
DRUG TARGETS				
VKORC1[66,117]	Warfarin	Single nucleotide polymorphism: 1639 G>A	Increase risk of bleeding	Monitor INR more frequently, and adjust dose accordingly
G6PD[126]	Rasburicase and dapsone	n/a	Increase risk of hemolytic anemia	Rasburicase is contraindicated when G6PD is deficient
HLA[13,127,128]				
_B*5701_	Abacavir	Presence of at least one _57:01_ alleles	Increase risk of hypersensitivity	Not recommended
_B*1502_	Phenytoin	Presence of one or two _57:01_ alleles	Increase risk of SJS and TEN	Dose adjustment is recommended
_B*1502_ _A*3101_	Carbamazepine	Presence of _*15:02 or *31:01_ alleles	Increase risk of SJS and TEN	Consider alternative therapy
_B*5801_	Allopurinol	Presence of at least one _58:01_ alleles	Increase risk of SJS and TEN	Contraindicated

CPIC = Clinical Pharmacogenetics Implementation Consortium, CYP = cytochrome P450, G6PD = glucose-6-phosphate dehydrogenase, HLA = human leukocyte antigen, INR = international normalized ratio, n/a = not applicable (no CPIC recommendation), SJS = Stevens–Johnson syndrome, SLCO1B1 = solute carrier organic anion transporter family 1B1, TEN = toxic epidermal necrolysis, UGT1A1 = uridine diphosphate glucuronosyltransferase 1A1, _VKORC1_ = vitamin K-epoxide reductase complex subunit 1.

DRUG TRANSPORT

Drug transporters are expressed in most tissues, including the liver, intestine, kidneys, and the brain.[61,62] They play a role in drug disposition by controlling the uptake and efflux of drugs in cells and by facilitating the movement of drugs between tissues and organs. Drug transporter function can be altered by many factors, including genotype. Organic cation transporter proteins (OCTs) are members of the solute carrier superfamily (SLC) of transporters. OCTs are uptake transporters that are predominantly expressed in the liver and kidney.

Cisplatin is a cancer chemotherapy agent that is widely used to treat solid tumors and is associated with nephrotoxicity and ototoxicity. Patients with minimal expression of both OCT1 and OCT2 or OCT2 alone are less likely to develop cisplatin-induced nephrotoxicity.[63] As an additional example, simvastatin is a widely prescribed medication for the management of dyslipidemias. Patients with polymorphisms in *SLCO1B1* (rs4149056T>C) are predisposed to simvastatin-induced myopathy. Thus, initiating simvastatin therapy with lower doses or considering an alternative agent is recommended in patients with this genotype.[64]

P-glycoprotein (Pgp) is an adenosine triphosphate (ATP)-binding cassette (ABC) transporter that (1) is expressed in the intestine, liver, and kidneys and also at the blood-brain barrier, and (2) protects against foreign substances through efflux from cells. Pgp promotes multidrug resistance by the efflux of pharmacological substrates from cells.[61,62] Pgp limits drug absorption via efflux of its substrates into the intestinal lumen, while in the kidneys and liver it promotes drug excretion into the ultrafiltrate and bile, respectively. Polymorphisms in the *ABCB1* gene have been demonstrated to decrease function and alter plasma drug concentrations by enhancing absorption, decreasing clearance and increasing access to the central nervous system. This may increase the risk of unexpected drug-related adverse events, particularly associated with the Pgp substrate digoxin.[65] The overall clinical relevance of polymorphisms in the *ABCB1* gene needs further delineation but could be an important factor for drug-induced diseases, particularly those associated with digoxin.

DRUG TARGET RECEPTORS

Genetic polymorphisms in drug targets—including enzymes, G-protein coupled receptors, ion channels, and other proteins—contribute to variability in drug efficacy and toxicity. The vitamin K epoxide reductase complex subunit 1 (*VKORC1*) gene encodes for the enzyme that is the primary pharmacological target for warfarin.[66] VKORC1 converts inactive vitamin K epoxide to active vitamin K, which is required for several coagulation factors including VII, IX, and X. An alanine (A) substitution for glycine (G) at position 1639 (1639G>A) in the *VKORC1* gene decreases the promoter activity and expression of VKORC1 protein. Thus, patients with the AA genotype require lower maintenance doses of warfarin and are at higher risk of warfarin-related adverse events, particularly in those patients that also carry reduced function alleles of CYP2C9 (i.e., *2 or *3).[54]

HUMAN LEUKOCYTE ANTIGEN

Several pharmacogenomic studies have demonstrated an important role for the HLA genes in what were previously considered idiosyncratic adverse drug reactions.[50] The major histocompatibility complex region, located on chromosome 6, contains HLA genes class I *(HLA-A, -B and -C)* and class II *(HLA-DR, -DP and -DQ)*, which are important for the function of the human immune system.[67] Several studies have shown various associations between HLA alleles and adverse drug reactions, the most common of which are liver injury and hypersensitivity reactions. The strongest available evidence associating HLA polymorphisms and drug-induced liver injury is with the antimicrobial flucloxacillin, tricyclic antidepressants, diclofenac, amoxicillin-clavulanate, and abacavir.

The most serious adverse drug events that have been associated with HLA polymorphisms are severe skin hypersensitivity reactions.[50] The hypersensitivity response is categorized as early or delayed.[68] The early response is mediated by IgE and the role of genetic polymorphisms in this type of reaction is unclear. The delayed response is T cell-dependent and varies from mild skin rash to very severe hypersensitivity syndrome. The most serious of these reactions affect other organs and tissues resulting in SJS or TEN.[50,68] Carbamazepine is the most commonly prescribed medication that induces SJS/TEN, which is strongly associated with the *HLA-B*1502* allele (rs3909184G>C and rs2844682G>A).[69] Asian populations are at higher risk of carbamazepine-induced SJS/TEN due to a higher allele frequency compared to other populations. The *HLA-A*3101* allele (rs1061235A>T) is associated with SJS/TEN in Caucasian patients, but to a lesser extent. The *HLA-B*1502* allele has not been linked to SJS/TEN in Caucasians due to a low expression frequency. This highlights the importance of the HLA genotype to predict hypersensitivity reactions in Asian populations, which is supported by a “black box” warning in carbamazepine labeling. Other important associations between the HLA genotypes and SJS/TEN, including abacavir, are provided in Table 3-1.[70,71] Pharmacogenetic testing is primarily used in patients of Asian descent to identify individuals at risk of HLA-associated adverse drug reactions prior to initiation of therapy with drugs that are known to induce serious hypersensitivity reactions.

DRUG–DRUG INTERACTIONS

DDIs refer to alterations in the effect of a medication (victim drug) when coadministered with another medication (perpetrator drug).[72] DDIs are the underlying factor in many drug-induced diseases and are attributed to as many as 26% of hospitalizations related to adverse drug reactions.[72-75] Classified by the mechanism that influences the action of the victim drug to increase susceptibility to drug-induced disease, DDIs are broadly divided into pharmacokinetic or pharmacodynamic interactions. Pharmacokinetic-based interactions affect the absorption, distribution, metabolism, or excretion processes, while pharmacodynamic-based interactions alter physiologic systems within the body.

The implications of DDIs on clinical practice are both profound and diverse:

- DDIs can be exploited clinically to achieve synergistic increases in drug efficacy, such as in the use of aminoglycoside and β-lactam antibiotics concomitantly to treat bacterial infections.
- DDIs can result in therapeutic failure, as manifested by the reduced anticonvulsant efficacy of phenytoin during coadministration with rifampin.
- DDIs can result in potentiation of the adverse effects of the victim drug to cause drug-induced disease, such as the development of digoxin-induced nausea, vomiting, anorexia, or arrhythmias when coadministered with amiodarone.

DDIs that result in potentiation of adverse effects constitute an important cause of drug-induced diseases and these interactions will be the focus of this section.

The effective identification and characterization of DDIs are critical to facilitate their prevention and to limit the incidence of drug-induced disease in clinical practice. A complicating factor of DDIs is that they can occur through the simultaneous action of multiple mechanisms. Due to these complexities, DDIs are sometimes difficult to identify and remain an important factor contributing to drug-induced diseases.

PHARMACOKINETIC DRUG–DRUG INTERACTIONS

The many clinical implications of DDIs reflect the vast range of physiologic processes and systems affected. Pharmacokinetic-based DDIs impact drug action by altering drug exposure within the body. Common mechanisms of pharmacokinetic DDIs that cause drug-induced disease, along with clinically relevant examples, are discussed in this section.

Membrane transporters impact the pharmacokinetics of many medications and, therefore, factors that influence transporter activity have implications on both drug efficacy and safety. As indicated in the Genetic Variation section, two important superfamilies of transporters that impact drug disposition include ABCs and SLCs, with members of these two superfamilies contributing to both drug influx and efflux from systemic circulation and/or the drug site of action. Inhibition of drug transport through these mechanisms can increase drug exposure.[76] An important DDI related to drug transporter inhibition involves the novel oral anticoagulant dabigatran when coadministered with a Pgp (member of the ABC superfamily) inhibitor. Serum dabigatran concentrations are elevated when coadministered with verapamil, an inhibitor of Pgp.[77] The decreased Pgp-mediated dabigatran efflux within intestinal epithelial cells increases the risk of major bleeding associated with dabigatran therapy.[78,79] Similarly, the incidence of respiratory depression associated with the antidiarrheal agent loperamide is increased when coadministered with the Pgp inhibitor quinidine.[79] The mechanism involves inhibition of Pgp mediated efflux at the blood-brain barrier. This enhances loperamide access to the central nervous system to precipitate respiratory depression.[80]

Modulations in the activity of drug-metabolizing enzymes are the most common and widely studied mechanism of DDIs. Most frequently, drug-metabolizing enzymes mediate the transformation of a pharmacologically active parent drug into less active or inactive metabolites. Therefore, factors that influence drug metabolism result in changes in exposure of active drug moieties, ultimately resulting in alterations in both the therapeutic and adverse effects of drugs.

The CYP450 enzyme system is primarily responsible for the biotransformation of drugs during phase I metabolism. Clinically relevant DDIs affect the following CYP isoenzymes: CYP1A2, CYP2B6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4/5.[81-83] Inhibition of CYP enzymes results in increased exposure of parent drugs metabolized by these pathways, increasing both therapeutic activity and the potential for adverse drug effects when the parent drug is the active moiety. Exposure to midazolam is increased during coadministration with the CYP3A inhibitor ketoconazole, resulting in the potentiation and prolongation of midazolam's hypnotic effect.[84] In addition, the induction of CYP enzymes may also precipitate drug-induced diseases. For example, induction of CYP2E1 by isoniazid results in increased metabolism of acetaminophen to its toxic metabolite, NAPQI, resulting in an increased risk for hepatotoxicity.[85-87] There are numerous examples of potential DDIs that precipitate drug-induced diseases. Some of the examples of DDIs involving the inhibition of CYP isoenzymes are displayed in **Table 3-2**.

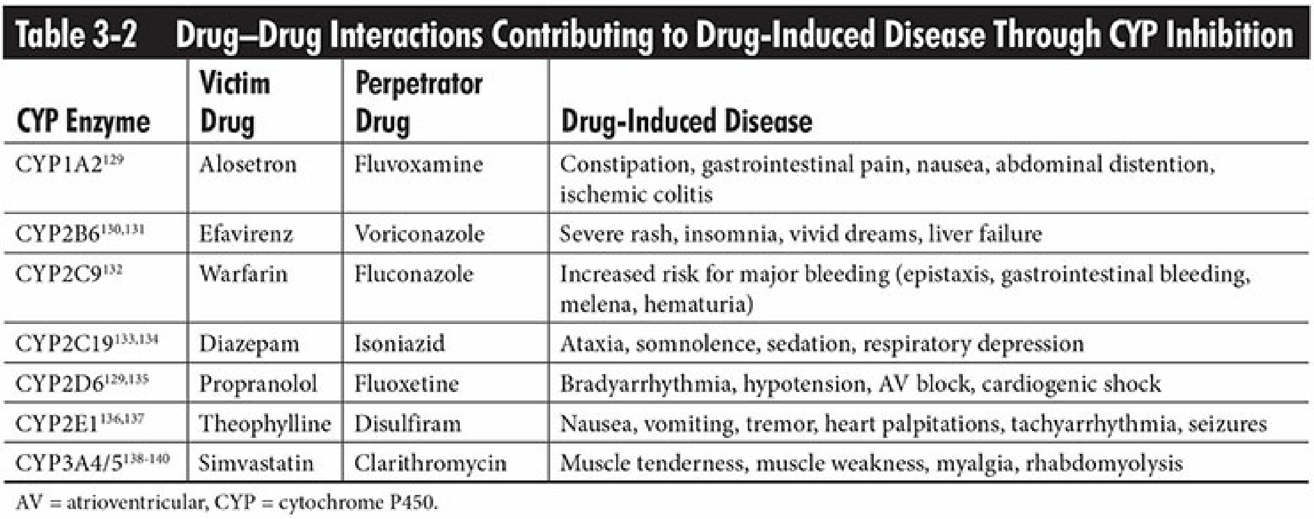

Table 3-2 Drug–Drug Interactions Contributing to Drug-Induced Disease Through CYP Inhibition

CYP Enzyme	Victim Drug	Perpetrator Drug	Drug-Induced Disease
CYP1A2[129]	Alosetron	Fluvoxamine	Constipation, gastrointestinal pain, nausea, abdominal distention, ischemic colitis
CYP2B6[130,131]	Efavirenz	Voriconazole	Severe rash, insomnia, vivid dreams, liver failure
CYP2C9[132]	Warfarin	Fluconazole	Increased risk for major bleeding (epistaxis, gastrointestinal bleeding, melena, hematuria)
CYP2C19[133,134]	Diazepam	Isoniazid	Ataxia, somnolence, sedation, respiratory depression
CYP2D6[129,135]	Propranolol	Fluoxetine	Bradyarrhythmia, hypotension, AV block, cardiogenic shock
CYP2E1[136,137]	Theophylline	Disulfiram	Nausea, vomiting, tremor, heart palpitations, tachyarrhythmia, seizures
CYP3A4/5[138-140]	Simvastatin	Clarithromycin	Muscle tenderness, muscle weakness, myalgia, rhabdomyolysis

AV = atrioventricular, CYP = cytochrome P450.

The kidneys play an important role in the elimination of many drugs. DDIs may potentially influence renal elimination and predispose individuals to drug-induced disease via four distinct mechanisms[88]:

1. Inhibition of tubular secretion, the process by which drugs are moved from the peritubular capillaries to the renal tubular lumen for excretion
2. Changes in urinary pH that decrease drug excretion
3. Changes in renal blood flow that decrease drug filtration
4. Inhibition of renal drug metabolism

Trimethoprim, when formulated with or without sulfamethoxazole, inhibits OCT2-mediated tubular secretion of the antiparkinsonian drug amantadine, resulting in increased amantadine exposure and the potential for psychiatric symptoms such as delirium, confusion, and combative behavior.[88,89]

PHARMACODYNAMIC DRUG–DRUG INTERACTIONS

The basis for pharmacodynamic DDIs involves alterations of pharmacological targets that accentuate or attenuate a physiological response. Such physiologic alterations are frequently related to the pharmacologic effects of the drug entities but also may occur via off-target effects. Thus, pharmacodynamic DDIs may result in reduced drug efficacy or enhance the risk for drug-induced diseases.

Additive pharmacodynamic effects constitute a very common cause of drug-induced disease. Clinically significant examples of additive pharmacodynamic DDIs include drug-induced hypotension in patients with heart failure as a result of coadministration of multiple agents with hypotensive effects, such as β-blockers, ACE inhibitors, hydralazine, isosorbide dinitrate, and angiotensin receptor blockers. Another example of a pharmacodynamic DDI that can result in a drug-induced disease is the coadministration of multiple drugs known to individually prolong the QT interval on a surface ECG, increasing the risk of torsades de pointes, such as coadministration of the fluoroquinolone levofloxacin, with the antipsychotic agent haloperidol.[90-92]

FOOD–DRUG INTERACTIONS

Food–drug interactions can result in drug-induced diseases. Similar to DDIs, food–drug interactions can occur as a result of the alteration of pharmacokinetic or pharmacodynamic processes due to an interacting component found in the diet. These interactions can contribute to the development of drug-induced disease through a variety of mechanisms, including opposition of a drug's therapeutic activity and potentiation of drug adverse effects and toxicities. Food–drug interactions present a necessary consideration, and their effect on drug action can influence both drug selection and dose determination. Three common and clinically significant examples of food–drug interactions that contribute to drug-induced disease are described below.

Tyramine is a monoamine compound found in aged food and beverage products like cheese and beer, respectively. A potentially life-threatening food–drug interaction occurs when the metabolism of tyramine is inhibited by the class of drugs known as the monoamine oxidase inhibitors (MAOIs), occurring most frequently with older MAOIs such as phenelzine, isocarboxazid, and tranylcypromine. The food–drug interaction dramatically increases tyramine's vasopressive effects and can precipitate severe hypertension, hyperthermia, cardiac arrhythmias, and cerebral hemorrhage.[93]

Caffeine—found in coffee, tea, cola, and chocolate—is involved in a variety of food–drug interactions based on both its pharmacodynamic profile and its similarity in structure and function to certain drugs. Caffeine consumption is contraindicated during use of the structurally similar methylxanthine drug, theophylline. Caffeine increases plasma theophylline concentrations and potentiates its numerous adverse effects. Additionally, caffeine administration has been demonstrated to reduce seizure threshold and may thereby precipitate seizures or diminish the efficacy of anticonvulsant medications.[94-96]

Grapefruit juice is a potent inhibitor of intestinal CYP3A4 metabolism, and it is also implicated in the inhibition of intestinal Pgp efflux transporters and organic anion-transporting polypeptide influx transporters through interactions mediated by furanocoumarin and flavonoid species found in the juice.[97] In fact, trials have demonstrated significant alterations in drug disposition upon coadministration of as little as one 8-ounce glass of grapefruit juice.[98] Food–drug interactions involving grapefruit juice affect a vast number of drugs that rely on the Pgp and CYP3A4 pathways for systemic absorption and metabolism, including antibiotics, antidepressants, antihypertensives, antiarrhythmics, corticosteroids, and medications to manage hypercholesterolemia.[97] For instance, the risk for myopathy and rhabdomyolysis associated with simvastatin may be increased when taken with grapefruit juice.[99]

MEDICATION NONADHERENCE

Medical nonadherence is defined as when patients do not follow provider recommendations about medication therapy with respect to timing, dosage, and frequency. It constitutes a major global healthcare problem and contributes to the incidence of drug-induced disease.[100] The World Health Organization proposes that increasing the effectiveness of adherence interventions may have a greater population-wide health impact than improvements in specific medical treatments.[101] This assertion is supported by recent estimates that as many as 50% of Americans are not adherent to long-term medication therapy, resulting in preventable annual healthcare expenditures of over $100 billion.[102]

The contribution of medication nonadherence to drug-induced disease occurs through a variety of mechanisms. One instance is when a patient nonadherently increases the dose or frequency of drug administration, resulting in enhanced drug exposure. Nonadherence can also contribute to drug-induced disease through indirect mechanisms, such as nonadherent behaviors resulting in decreased medication administration. For example, when a patient omits medication doses, the prescriber may intensify therapy either by increasing the dose or frequency of the medication or through addition of adjunctive medication therapy, thereby predisposing the patient to an increased risk of drug toxicities.[100]

The causes of medication nonadherence are often complex, multifactorial, and highly variable among patients. Six of the most commonly described factors contributing to nonadherence include the following[103]:

1. Lack of patient understanding of the contribution of medication adherence to continued good health
2. Patient perception that the potential risks of medication therapy outweigh the benefits
3. When the complexity of the medication therapy regimen exceeds the patient's mental processing capacity
4. Lack of sufficient patient vigilance
5. When the patient possesses inaccurate, irrational, or conflicting normative beliefs regarding medication therapy
6. Patient disbelief in the therapeutic efficacy of a medication

Addressing the specific cause of patient nonadherence is paramount to effectively improving adherence. Accordingly, strategies to improve medication adherence have focused on combinations of multiple interventions to address the many reasons for nonadherence. For example, patient counseling and provision of health information may improve patient understanding of the benefit and efficacy of medication in promoting health. Interventions such as electronic reminders to take medicine and medication packaging with a calendar feature help increase patient vigilance.[104,105] Despite these multifactorial approaches, strategies to improve adherence have generally demonstrated only modest increases in adherent behavior.[106] As a result, medication nonadherence remains a significant challenge to effective medication therapy and an important factor to consider in relation to drug-induced diseases.

MEDICATION ERRORS

Defined as "any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the healthcare professional, patient, or consumer," *medication errors* constitute a significant cause of drug-induced disease.[107] Medication errors are commonly manifested as administration of the wrong drug, drug overdoses, overlooking of documented patient drug allergies, or failure to detect DDIs—all of which can directly cause adverse drug events.[108] The estimated medication error rate is at 1.6 errors per 1,000 patient days in adult hospitalized patients. This rate is elevated in special patient populations, such as an estimated rate of 13.4 errors per 1,000 patient days in pediatric patients.[109,110]

Medication errors may occur during any step of the medication-use process, including prescribing, transcription, dispensing, administration, and monitoring. A series of studies by the Adverse Drug Event Prevention Study group attributed 28% of discovered adverse drug events to medication errors during a 6-month investigation within two major metropolitan hospitals.[111] The medication errors were most likely to occur during prescribing (56%), administration (34%), transcription (6%), and dispensing (4%).[112] The National Coordinating Council for Medication Error Reporting and Prevention has developed an index for categorizing medication errors based on whether a medication error reaches the patient, whether the error results in patient harm, and the severity of managing the adverse drug event.[113] The index seeks to provide a systematic means to standardize the classification and severity of medication errors to more accurately characterize their burden to medication use.

As medication errors occur over a wide variety of steps in the medication-use process, the reasons that they occur are widely variable. Risk factors that predispose patients to medication errors can be patient-specific (kidney or liver disease, advanced age), prescriber-specific (use of potentially confusing medical abbreviations when prescribing), or factors latent within an institution's system of delivering patient care (poorly structured physical or informational environment, failing to adhere to clinical standards).[114,115] Regardless of medication error etiology, properly identifying the causes is essential in preventing error occurrence.[116] The FDA has instituted efforts to prevent medication errors such as the widely implemented 5 Rights of Medication Administration. The effective use of information technology within the administration of healthcare has been perhaps the greatest advancement in preventing medication errors, as electronic technology has the potential to significantly reduce errors in all steps of the medication-use process.[115] Although the contribution of medication errors to the development of drug-induced disease is well evidenced, strategies for preventing these errors remain a formidable challenge.

SUMMARY

This chapter outlines the most important factors that are known to contribute to drug-induced diseases while demonstrating important clinical consequences. The contribution of age, sex, race, pregnancy status, genetics, comorbid diseases, cigarette smoking, alcohol, illicit drug use, DDIs, food–drug interactions, medication adherence, and medication errors should all be considered to identify the potential for a drug-induced disease.

CHAPTER 4

Postmarketing Surveillance for Drug-Induced Diseases

Tobias Peschel and Hugh H. Tilson

The job of ensuring safe therapeutics extends far beyond the drug development, premarketing period. Sustained postmarketing monitoring (surveillance) activities are critically important because premarketing investigation alone cannot define completely the safety profile of a drug. Responsibility for overseeing postmarketing surveillance falls to the U.S. Food and Drug Administration (FDA) in the United States (and comparable divisions of regulatory agencies around the world). However, as in all public health enterprises, the work of postmarketing surveillance is shared by the full spectrum of the healthcare enterprise—from the patient and the individual prescriber, academia and healthcare organizations, to the manufacturer and regulatory agencies. Postmarketing attention to drug-induced diseases encountered in day-to-day practice is the responsibility of every healthcare practitioner and his or her patients. Independent clinical observations and voluntary reporting to manufacturers and regulatory agencies are at the heart of population-level surveillance. However, systems that rely solely on individual observation and voluntary reporting fall short. No individual clinician or patient can be expected to recognize rare drug-associated events and unusual patterns from limited individual experience. Thus, more structured population-based programs of postmarketing surveillance for drug-induced diseases, including structured epidemiological studies, are essential components of our nation's broader public health efforts. The promise of larger and more accessible population-based data for this purpose is great but requires concerted effort to ensure acceptable population-level protections.

RECOGNIZING THE LIMITS OF PREMARKETING DATA

When a drug is approved for marketing under the provisions of the Food, Drug, and Cosmetic Act (FD&C Act), or abroad under similar laws around the world, the product is deemed to meet several official requirements, which often are stated in shorthand as "safe and effective." However, the meaning of that phrase is widely misinterpreted. There is not a broad understanding among the medical community of the burden of proof required to obtain FDA approval to market a drug.

The sponsor of the New Drug Application (NDA) must demonstrate that the product is *efficacious*, usually through well-controlled studies. The approval processes around the world typically require completion of two randomized, blinded, well-controlled clinical trials, with clear separation of efficacy endpoints against placebo when possible or against a rigorous, appropriate standard intervention that is already approved.[1] Thus, the sizes of the preapproval populations under observation are driven by the power of trials to achieve these requirements. Far less clear are the preapproval standards for proof of a new drug's *safety*, distinct from its efficacy. In general, the profile of adverse effects associated with the agent, both self-limiting side effects and serious unexpected and untoward effects induced by the drug, must be such that the threat of these adverse effects is not proven to outweigh the drug's likely benefit. Practicality and necessity often temper the stringency of this requirement in a number of ways. Generally, the number of persons exposed to a new drug before approval for marketing is granted may be as few as 2,000 or 3,000.[1] Indeed, it can be even only a few hundred individuals in the case of orphan drug designation for the treatment of a rare, "orphan" condition. Under these circumstances, the apparent absence of unacceptably frequent or intolerably severe adverse outcomes of treatment can provide only statistical assurance that the likelihood of such drug-induced illnesses, if they exist, is less than about 1/1,000. Moreover, the duration of such preapproval studies is generally only as long as is needed to comply with FDA requirements to meet the prespecified endpoints for efficacy. Thus, the occurrence of an excess of heart attacks following 18 months of therapy could not be detected even in a relatively large preapproval database of studies of 12-month duration. These limitations could be expressed as the *Rule of Too*: to depict population level safety, the preapproval experience alone is too small, too brief, too healthy, and too homogeneous. Absence of data does not prove absence of a problem.

The research environment of the randomized, blinded, well-controlled study further limits what we can know about the new drug's performance in wider clinical use following its approval. Naturally, preapproval studies generally are conducted under tightly controlled circumstances, with carefully designed protocols that exclude patients who appear to present the threat of confusing results. These can include patients affected by concurrent illnesses, taking concomitant medications, and with specific risk factors, or patients belonging to potentially risky population strata, such as the poor, ethnic minorities, children, pregnant women, and the elderly.

In summary, our understanding of the probability (risk) of incurring a drug-induced disease from a newly approved drug is limited by the nature of the system for premarketing study and the approval process.

THE NEED FOR POPULATION-BASED SURVEILLANCE FOLLOWING MARKETING

Systematic approaches to detection, quantification, and education concerning drug-induced disease following marketing have emerged only relatively recently with the advent of clinical trials approximately 50 years ago. Then, as now, the medical community educated itself largely by means of the published word, via clinical and scientific journals. Before randomized, controlled clinical trials were introduced, this "education by publication" typically took the form of anecdotal case histories, describing incidents of illness following drug therapy, where the drug was blamed for the undesired outcome. As part of the reform of the FD&C Act, voluntary reporting of such experiences to the FDA or the manufacturer was introduced as a fledgling surveillance system. The logic for such a system is that the only way to know of potential drug-induced problems that are unlikely to be detected in the preapproval drug development process is to monitor real-world experience after introduction of those products into the marketplace.

The cornerstone of population-based surveillance for medication-induced illness, as with public health monitoring of many emerging problems, is the technique of encouraging all practitioners to participate in a system of spontaneous voluntary reporting. Here the logic is to invite a heightened awareness, particularly regarding new drugs, that adverse outcomes following therapy—particularly those that are otherwise unexpected—may be attributable to the therapy. Therefore, if there is any index of suspicion, any member of the medical team, as well as the patient or his or her family, is encouraged to report, albeit on a voluntary basis.

Clinical detection of any single drug-induced disease or injury in a single patient may be extremely difficult. An immediate anaphylactic reaction to a drug may leave no doubt about its attribution. However, in most cases, drug-induced illness does not manifest itself differently or in dramatic ways from any illness that may be observed in a physician's office or pharmacist's practice. Sudden death, liver or kidney disease, encephalopathy, myocardial infarction, and other events may occur without any likely precipitating event or exposure. Even Stevens-Johnson syndrome, often thought of as a classic drug-induced disease, has as its two most frequent causes—"cause not apparent" and viral infection—with drug-induced problems listed third.[2] Thus, the experiences of the individual clinician alone are inadequate for providing information about population-level issues regarding drug-induced disease, such as prevalence, likely presentation, resolution, and long-term consequences. On one hand, a clinician witnessing one or two dramatic adverse events following the use of a specific drug may consider that drug a "bad actor" when the events may have been a rare coincidence or perhaps not drug-related at all. On the other hand, having never had a problem with the drug may simply be a function of the rarity of the drug-induced illness, the luck of the draw, or a failure to link the kidney disease in a patient or two with the drug or drugs they were taking. There is, in short, no substitute for population-level surveillance to determine the presence or absence of relatively rare problems or an increase in the rates of occurrence of otherwise not-so-rare adverse events over baseline. Thus, as in other public health enterprises, the aggregate experience in a population serves as the most effective sentinel or signaling tool for possible problems.

THE SPONTANEOUS REPORTING SYSTEM IN AMERICA

In this book, we differentiate between adverse drug reactions (ADRs), also referred to as adverse effects or side effects, and drug-induced disease. However, in every sense, the latter are a subset of the former. Thus, our primary system for detecting and tracking drug-induced diseases at the national level is the spontaneous adverse reactions reporting system (SRS), which is the nation's system for tracking all ADRs. Many have criticized the system as a "nonsystem," comprising a loosely administered chain of events in which those in positions to detect ADRs—the patients and the clinicians who work with them—are encouraged, voluntarily and without incentive, to call such incidents to the attention of those who are in a better position to assemble, analyze, and act on the ADRs. Indeed, the activities constituting the SRS are not systematic and are not integrated into the rest of the nation's systems of public health and safety surveillance and intervention/protection. As a result, the protections that this component of the nation's surveillance systems may provide are not guaranteed.

For the system to effectively capture and apply data concerning ADRs, a certain chain of events must transpire. Someone must detect that an adverse event has occurred in association with a drug exposure (an adverse drug event, or ADE) and must suspect that the adverse event might be causally associated with a drug exposure, converting the experience from an ADE to a suspected ADR.[3] This detection and interpretation must then be translated into action—the act of reporting the event, usually to an unseen, remote recipient. This event must be communicated to someone in the system who decides whether to incorporate it with information from other major sources—in the United States, typically either a government agency such as the FDA's MedWatch system, the Vaccine Adverse Event Reporting System, or one or more intermediaries. The primary such intermediary in the United States is the research-based, brand name pharmaceutical company. Pharmaceutical manufacturers receive, process, manage, analyze, and report well over 80% of all ADRs that eventually come to the attention of the FDA.[4] For manufacturers, further ADR reporting spontaneously and voluntarily from the field is mandatory.

In principle, the SRS also could recognize unintended but positive effects such as the unexpected hair growth observed with minoxidil, which led to the development of Rogaine and the sustained penile erection observed as an unexpected side effect of an antihypertensive drug, which eventually became sildenafil (Viagra). Bleeding reported following aspirin use led to eventual understanding of its cardioprotective effects.

THE ACTORS AND THEIR ROLES

It is worthwhile to examine the roles of each of the personal "actors" and the processes involved in the postmarketing surveillance process and explore some of the challenges involved in linking them into an effective system.

THE CLINICIAN

The point of departure for surveillance in the SRS is the reporter—the person, usually a clinician, who recognizes that something untoward, unexpected, and generally unwanted has occurred and suspects that the event is associated with a drug. A patient can introduce this information into the SRS either by reporting it directly to the manufacturer or a regulatory agency via a consumer report or by seeking medical care and calling it to the attention of the provider. Most providers—physicians, nurses, dentists, and pharmacists—claim they have not been trained sufficiently in the detection, management, and reporting of ADRs to function effectively as reporters in this system. Indeed, most indicate they have not reported a single ADR in the past year and they would not know how to report one if necessary.[4] Moreover, most providers state they see very few ADRs in their practice despite the nature and frequency of drug-associated adverse events. Many health profession educators attribute the lack of awareness of ADR prevalence on the failure of health curricula to educate emerging clinicians on the critical balance between a systems-thinking sensibility and the traditional art-and-science approach. More recently, the Association of American Medical Colleges has acknowledged the lack of broad consensus around the competencies required to be taught in professional education for effective participation in the nation's drug safety system. Epidemiology and statistical/probabilistic thinking are important competencies. The result has been a far-reaching comprehensive inventory of such competencies to be incorporated in all training programs.[5]

It also must be noted that very few drug-induced diseases are unique clinical entities. Rather, drugs are partially or broadly responsible for causing or aggravating many common clinical conditions. Identifying drugs as a potential cause requires complex clinical analysis. Furthermore, the drug may have been obtained through another prescriber, self-prescribed from the home medicine cabinet, or combined with an alternate or complementary medicine (prescribed or otherwise) or an unusual or unexpected dietary pattern. The patient may not have adhered to the recommended regimen, resulting in overdosing, underdosing, or (most commonly) episodic dosing, the latter two resulting in the adverse outcome of unexpected or periodic treatment failure. The patient may not recall fully or accurately which medications he or she has taken, or in what quantity, or in the case of illicit drug use, may not wish to disclose it. And, of course, the patient is generally taking medications to treat an underlying or coincident/concomitant illness, the progression of which may be confused with the drug-attributable illness. Clearly, identifying or preventing drug-induced disease requires a partnership between patient, physician, and pharmacist based on full disclosure, open discussions, and awareness of potential risk factors.

The clinician must not merely recognize the illness, but also must go through the process of differential diagnosis and analyses of potential underlying or precipitating factors other than drugs, after which the potential role(s) of drugs in disease need to be considered. This is no easy task, particularly given that the complexities of clinical pharmacology are themselves rapidly evolving. Having made a provisional association between drug and disease, the first concern of the treating provider is to remove and/or counter the offending agent. Simply achieving this goal easily can occupy the whole of a 15-minute patient visit, without the burdensome administrative tasks of reporting to some invisible and remote third party. No economic incentive exists to do so either, as voluntary reporting is expected to be done pro bono. Indeed, reporting an incident likely will generate subsequent questions and requests for more data from the agent receiving the report, creating a potentially significant inconvenience, which could discourage reporting. In the wake of the Institute of Medicine's (IOM; now the National Academy of Medicine) *To Err Is Human* report, we are admonished not to "name, blame, or shame" those who report and attempt to repair errors (in this case in prescribing, warning, or monitoring).[6] Nevertheless, admitting to a decision that caused an adverse outcome could result in a lawsuit or other censure. Widespread physician dread of current tort law and widespread stories of unjustified legal settlements does little to allay this anxiety or encourage reporting. The extent to which these barriers contribute to under-reporting is not known. Based on populations monitored prospectively and objectively, the under-reporting ratio for severe or serious ADRs (actual illnesses induced by medications) is estimated to be tenfold or worse.[7]

THE PATIENT

The patient is the point of departure for the postmarketing surveillance system. Preventing drug-induced disease in the individual patient through awareness of the likely consequences of specific circumstances, such as risk factors and drug interactions, requires a partnership between the physician, pharmacist, and patient and must include full disclosure, open discussion, and awareness of potential risks. In addition, the patient may be a direct reporter of potential drug-induced disease. The SRS receives reports from patients or their advocates every day; up to 20% of reports are from patients/consumers.[8] Although good surveillance practice recommends that patients be referred to a primary caregiver when making a report directly, the Council for International Organizations of Medical Sciences (CIOMS) working group concluded that it is the quality of the report and not the nature of the reporter that is essential.[9] Thus, while in Europe, until recently, consumer reports were generally not included in the SRS, consumer reports have been included for many years in the United States and Canada. The newly emerging European Guidance aligns with these approaches.[10] Thus, patient education regarding potential drug-induced illness and heightened awareness of reporting avenues and action result in a stronger likelihood that the SRS will learn about important drug-induced diseases directly from the patient.

THE MANUFACTURER

In the United States, a much misunderstood and generally underestimated factor in the SRS is the role of the entity marketing the drug (particularly in the early stages of marketing)—the research-based pharmaceutical company. In the regulatory context, these companies also are referred to as sponsors because they sponsor NDAs. The sponsor is responsible, under federal law, for compliance with all applicable federal regulations relating to the safety, efficacy, and purity of its products. These requirements include the conduct of regular ongoing product surveillance.[11] Under these provisions, the sponsor is expected to maintain vigilance regarding the safety of its products, including receipt, management, and further reporting of all ADRs from any source, including the published literature, ongoing clinical trials, and, primarily, the reporters who use, manage, and prescribe their products, as described above. Under the applicable regulations, sponsors are expected to maintain a program that provides an immediate review of any report received from any source, and they can differentiate the serious event from the nonserious. These tasks and definitions are carefully defined in FDA regulation and the subject of the CIOMS international consensus reports and international management agreements under the International Conferences on Harmonization.

Any report that comes to the company's attention through a spontaneous, voluntary report or product complaint is considered, by definition, potentially attributable to the product(s) involved. If the report also meets the criteria for serious or potentially serious effects and involves one or more events/signs/symptoms that are outside the specific listings in the approved product label (i.e., "unexpected"), such a report must be transmitted to the regulatory authority immediately.[11] This requirement is not limited to the United States as the regulations speak specifically to products sold anywhere in the world. Thus, any report documenting a serious event outside the product label (unexpected, unlabeled, or unlisted, and received by the company, its affiliate, or its agent anywhere the drug is marketed) requires immediate transmittal to FDA. Furthermore, such cases also require sponsors to analyze the completeness of the description carefully and follow up on incomplete data or information needed to ascertain severity and outcome with serious drug-associated illness. Regulatory definitions clearly distinguish between severity (the extent or intensity of the event) and seriousness (the medical impact of the event and its associated outcomes, including the potential for hospitalization or death if not adequately treated). Enough information is needed to help with causality assessments for the individual case and risk factor assessment for evolving case series. This latter requirement results in contacting the reporting practitioner for more information. The CIOMS Working Group has outlined best practices for pharmacovigilance to provide guidance for sponsors in their vital roles in this public health paradigm.[9] These best practices include regular, scheduled, comprehensive reviews of each of their products. The sponsor prepares a summary report for every drug, currently known as a Periodic Safety Update Report, which describes the overall experience over a particular period of time and in the population under surveillance.

The modern scientific research-based pharmaceutical company provides a broad spectrum of services to the healthcare community, including drug information services that constitute a primary interface between the company and healthcare practitioners. A physician, nurse, dentist, or pharmacist may contact the company for information regarding its products and accumulated reported clinical experiences or new information regarding their use. Typically, the purpose of the call is not really to report anything but to learn more about the drug product in question and its use. It is a requirement that the contact be viewed as spontaneous and that information about associated adverse events mentioned by the reporter be considered possible ADRs. In fact, it is not infrequent that during the course of such calls an ADR is revealed. Thus, the better the drug information system, the more calls it receives, and more reports of potential ADRs are generated. This process can introduce significant bias by creating an artifact in the numerator as one attempt to evaluate the relative incidence of ADRs is associated with a particular drug. As communications using web-based social media increase, the reporting criteria for a drug-induced disease will require careful scrutiny and regulatory clarification.

THE REGULATORY AUTHORITY

Ultimately, all ADR reports arrive at the responsible regulatory authority office, either by direct submission (although this is becoming less common) or through the responsible intermediary, the sponsor company. In the U.S. public health model, the role of the government is to ensure conditions in which people can be healthy, a role that requires healthy and active partnerships between government and the private sector, which in this case is the regulated pharmaceutical industry.[12] In recent years, regulatory agencies around the world communicate with each other and share information about drug-induced diseases reported to them. Within the FDA rules, companies notified from abroad are required to handle and report these ADRs as they would domestic reports. The challenge of managing duplicate reporting from multiple sources is always present in the FDA's approach to data management and analysis.

The FDA is the ultimate arbiter of a company's adequacy concerning compliance activities, both on a macro report-by-report level and overall as a partner in public health protection. Each report receives triage in the agency. Serious reports, such as those describing reactions most likely to result in drug-induced disease or injury, receive priority attention, particularly those that also qualify as unexpected. Each sponsor also receives compliance oversight from the agency, including a program of FDA site visits and compliance audits to ensure an intact reporting system with full transparent disclosure from sponsor to agency.

Attribution of a problem being considered for an ADR report requires the clinician to consider the possibility of a causal relationship to a drug, in the context of multiple other possible causal explanations for the same events. Rarely is such a causal relationship unambiguous. Rather, the clinician must apply complex logic, including consideration of the timing of the event, the presence of other possibly causal exposures, the natural history of the underlying disease, and so forth. The SRS operates on the fundamental assumption that a report would not present to the system unless a reporter had some concern or suspicion about a possible causal relationship to the drug. Thus all SRS reports are considered possibly attributable. The evolution of the system, however, brings this assumption into question. More and more, for example, information comes to the attention of the system because of proactive study or detailed information seeking in association with an individual report or engagement with social media. This challenges scientists and practitioners involved in the science of surveillance to differentiate between truly spontaneous and possibly attributable reports and those reports that are elicited.

The pivotal role of the FDA in this public health system has made it particularly vulnerable to public criticism. Recent concerns about unexpected serious drug-induced diseases being undetected for too long (e.g., cardiovascular disease associated with rofecoxib and celecoxib, suicides associated with selective serotonin receptor inhibitors) resulted in the FDA Commissioner's request to the IOM of the National Academies of Science to conduct a thorough ongoing study of the system and the FDA's roles and contributions. In its landmark report, *The Future of Drug Safety*, the IOM calls for sweeping reforms in the way FDA approaches its roles, and specifically defines the critical changes necessary to promote the creation of a new "culture of drug safety."[13] In this new culture, public health efforts at detection of and protection against drug-induced diseases must assume a position equal in importance to those of the review and approval of new drugs.

THE SCIENCE OF SURVEILLANCE

SPONTANEOUS REPORTING

Surveillance is one of the tools of epidemiology, the fundamental science of public health, and the core tool for public health assurances in the pharmaceutical sector. Paradoxically, the surveillance activities in this sector are separated from those at work throughout the rest of the public health landscape. Most public health surveillance activities in the United States are a function of state and local public health agencies. Surveillance information about acute diseases of epidemic potential is consolidated and managed by each of the 50 states and forwarded to the Centers for Disease Control and Prevention (CDC) for aggregation and national reporting through such vehicles as the *Morbidity and Mortality Weekly Report*, and, more recently, the Health Alert Network.

By accident of historic evolution, surveillance for drug safety, and more recently for medication errors, has been handled in the parallel universe of pharmaceutical manufacturers and the FDA. The tools and their applications, however, are remarkably similar to those used in other sectors of public health. Each system designates events of interest. In the case of the CDC, these are reportable suspected cases of infection of epidemic potential, or more recently, conditions of potential for chronic disease epidemics. For the FDA, they are suspected cases of drug-induced disease that could signal potential problems for others taking the drug. Each surveillance system (1) attempts to learn as much about each case as is feasible within the constraints of voluntary reporting; (2) seeks to discern aspects of the case that might give an indication of unusual or unique circumstances (risk factors) to aid in understanding the extent of risk to others; and (3) attempts to develop some estimate of the frequency and evolution of the cases to define the gravity of the public health threat. Thus, a central requirement of both surveillance systems is the participation of well-trained, vigilant public health professionals. These professionals ensure that case reports are analyzed singly and in aggregate by the trained eyes of those who understand the subtleties of epidemiologic signaling systems and can detect patterns and parallels of data gathered from disparate sources.

INDIVIDUAL CASE AND POPULATION-BASED ANALYSIS

The report rate is a key subtlety of the system. Rate calculations require both a numerator (the reported cases) and a denominator (the exposed population). Calculating these elements within a voluntary reporting framework is an intrinsically uncertain process. Whenever surveillance data are accumulated under such voluntary circumstances, inevitably many variations exist in what is reported. When, by whom, to whom, and how reports are submitted become critical elements in surveillance analysis. Put another way, the surveillance numerator, based on voluntary reports, captures a further subset of all such events—those the physician or pharmacist are willing to take the time and trouble to report from among the larger subset of events. Various environmental factors influence reporting and, consequently, may periodically and temporarily change the signaling capacities of the system. A recent journal or newspaper report can cause a cascade of interest and reports from the field, and the passage of time is a well-known cofactor of declining interest in reporting. The emergence of drug information services within industry compounds the challenge and impacts the numerator as described above.

Calculating the denominator—the population exposed to a drug—also is a challenge. Many drugs are “sold” from company to distributor but remain somewhere in the supply pipeline not yet available to patients. Much is prescribed but never dispensed; much is dispensed but never taken. Therefore, efforts to estimate the population exposed requires sophistication and estimates must be used carefully and with many caveats. Thus, the surveillance practitioner must be trained carefully to understand and recognize these factors when attempting to generalize from individual reports to a concern about increased incidence of such reports over a population-expected baseline. The trained professional in the drug-induced disease world refers to reports rates and not incidence when discussing these reports and their trends.

PROACTIVE/SENTINEL SURVEILLANCE

Because of the weaknesses in the existing SRS, many have suggested a more aggressive effort at monitoring populations using methods beyond voluntary reporting, once again turning to the time-honored methods of public health epidemiology. The field specializes in epidemiologic population-based research methods coupled with public health approaches to spontaneous reports, which has been termed *pharmacoepidemiology*.[14,15] Intensive inpatient monitoring, the first major such scheme, was very productive in detecting unexpected increases in the frequencies of otherwise expected diseases in association with drug use, permitting statistical associations to generate signals.[16] However, such systems have proven expensive and limited in numbers of individuals exposed, particularly with new drugs, and have fallen into disuse except as ad hoc studies focused on specific new drugs with an intense effort to discover the degree of exposure nationwide.

LARGE AUTOMATED MULTIPURPOSE POPULATION-BASED SYSTEMS

Contemporary healthcare operates within a continuing revolution in medical informatics, fueled by the advent of large automated databases that support automated medical records, computerized prescribing, and wireless hand-held devices in ambulatory medical practice. As a result, many large components of the healthcare delivery system have automated data describing every drug prescribed, every subsequent major diagnosis associated with a hospitalization (admission and discharge), and, of course, longer term monitoring for late or latent outcomes available to them. These data sets are known as large automated multipurpose population-based systems (LAMPS). LAMPS already have amply demonstrated their value as tools for the pharmacoepidemiologist to use when conducting formal observational studies to test signals from other systems, such as the SRS.

LAMPS, however, have several critical limitations as surveillance tools. The power of a signal generator is tied directly to the size of the exposed population. Thus, a database owned by a single health maintenance organization (HMO), even one reflecting the medical transactions of millions of enrolled individuals, may not include enough exposures to any single drug to detect any but the most commonly associated drug-induced diseases. This includes any new drug in the early phases of marketing and is particularly true in key population subgroups for which a possible increased risk of medication-induced illness may occur.

Public health objectives must be kept clearly in view. Society has the responsibility to monitor for drug-induced diseases that are sufficiently severe to create an unacceptable burden on individuals or that are serious and frequent enough to create a public health burden. For the former, a system to detect the very rare but unacceptably severe reaction is needed. For this, the SRS, with all of its faults, is the only existing tool that can be considered adequate. But for the latter, monitoring and quantitating the occurrence of excess medical adversity risk and documenting excess morbidity, mortality, and cost to society will permit us to accomplish society's public health surveillance tasks. With these objectives clearly in mind, the IOM called for the aggressive development of programs of automated population-based "active surveillance."[13] In response, in the FDA Authorization Act (FDAAA; 2007), Congress mandated the FDA to develop a sentinel surveillance system based in automated population-based data systems with the objective of monitoring a population of 25 million by 2010 and 100 million by 2012.[17] This dramatic vision has spawned major activity across the breadth of the public health system, with emerging LAMPS now recognized and harnessed for drug safety surveillance as well as research. Major health plans, including United Health Care, Wellpoint (Blue Cross/Blue Shield), Aetna, and the collaborative HMO Research Network, among others, have made data available to leading researchers for such explorations.

Academia, in its critical role in the public health system, has organized centers of excellence, such as the Centers for Education and Research on Therapeutics (CERTs) program to assist the FDA in this endeavor.[18] The CERTs convened a think tank to outline the steps forward.[19] Industry, as a key partner in the system, organized and funded (through the Foundation for the National Institutes of Health) an independent effort at testing new methods for cross-system data summary and analysis for prospective (sentinel) development of signals of potential drug-induced diseases (the Pharmaceutical Manufacturers' Association Observational Medical Outcomes Program).[20] In addition, the FDA itself organized and managed a vigorous process for exploring the path to responding to the FDAAA mandate for sentinel surveillance, deemed the *minisentinel*.[21] After 5 years of progressive growth and proofs of concept, the project was adopted in September of 2014 as a standing FDA effort known as the FDA Sentinel Network.[22] The network deploys a distributed data system from 18 organizations including some of the nation's largest health insurers and various disease registries. The FDA and its collaborator, Harvard Medical School, estimate that the system is now capable of monitoring drug exposure for 178 million people, with 48 million currently enrolled/treated, and a growing ability to link drug exposure with validated medical events data, including hospital diagnoses.[22]

In addition to ADRs as a result of the drug, it is also important to monitor potential harm caused by unintentionally administering the incorrect drug (e.g., due to similarities in names or poor legibility of a prescription, or errors along the chain from prescription to patient). This special situation of medication errors demands a third monitoring method. But what system exists to monitor, compile, analyze, and develop proper interventions regarding these errors? Part of the nation's response has been developing institution-based reporting and continuous improvement systems. These are vital because root causes can be locally identified and remedied in institutional systems and practices. They are inadequate, however, in detecting flaws in product presentation or design, name confusion, look-alike packaging, or confusing product information. For these, integration into a more comprehensive national detection system is also required. Therefore, several key leadership organizations have taken decisive action. Notable among these is the MEDMARX system (Quantros, Inc., Milpitas, CA).[23]

THE WAY FORWARD: CAN YOU IMAGINE?

Protecting society against preventable drug-induced diseases and device-associated injury, through early detection of possible problems emerging from therapies, is the primary objective of a public health-oriented drug safety surveillance system. Such protections require, at the population level, an affordable, effective system of monitoring for serious adverse events that occur in the population in excess of what would be expected from disease and natural causes alone. To achieve this objective, progress is needed on three fronts. First, the reporter must be more attuned both to monitoring for possible drug-induced illness and to reporting it effectively. Second, the system needs to be more efficient in retrieving and managing the resulting data and more effective in harnessing it to existing systems of surveillance. Finally, new technologies, made available through the rapid dissemination of automation into medical practice, must be harnessed to the task effectively.

These goals, in turn, require three ambitious sets of activity. First, medical, pharmacy and other health professionals must do a better job of reaching the practitioner with salient messages about drug-induced diseases and with convincing efforts to harness the time and energy of the busy practitioner. We need to do a better job of incorporating these tasks, and the competencies which underlie them, in undergraduate and postgraduate training of our professionals. Continuing education credit for participating in the SRS has been suggested as a promising incentive. But an even more promising strategy is to make the act of reporting one that reaps rewards in terms of useful information to help care for the patient at hand and the other patients under the care of the reporter. Can you imagine a truly easy, user-friendly, and useful system populated by truly public health-oriented satisfied reporters?

Second, public health agencies, notably the CDC and FDA, working with state and local public health surveillance professionals should undertake a thorough and systematic examination of existing methods of population-based surveillance to better align systems and the incentives to strengthen them. Although the SRS may be the most powerful generator of warnings of rare but unacceptable toxicities, better integrated and aligned signal generators are needed for drug-induced diseases that, while possibly less severe, are occurring at greater frequency in the population at large. Certainly these include preventable errors in the use of medications and their avoidable consequences. Can you imagine a truly seamless and integrated system of surveillance for *all* problems of public health importance?

Finally, those working in the field of information technology to support medical practice—such as those involved in developing and promulgating the automated medical record, personal digital assistant, and other hand-held technologies—need to work together to build data systems that are compatible with efficient and accurate conduct of the medical purposes for which they are intended. Equally critical is the development of data standards and refinements needed to provide the public health surveillance system (and, of course, the research enterprise) with the data needed to perform these vital functions in a timely, effective, and affordable way through the game-changing Sentinel Network project. Can you imagine a national surveillance system that does not require therapy team members to report information and to recall where to submit it because the automated system that supports their transactions can do this for them? Can you imagine a system that minimizes the administrative tasks and maximizes patient well-being, perhaps even one that is capable of "finding" problems before they become apparent and enabling us to prevent them from becoming major public health problems? Please imagine these changes as they are vital to a well-functioning integrated, proactive system of postmarketing surveillance. True public health protection requires it.

CHAPTER 5

Evaluating Patients for Drug-Induced Diseases

Douglas A. Miller and James E. Tisdale

As discussed in Chapter 2, there are thousands of drugs and drug products available on the market today. Nearly 60% of American adults take at least one prescription drug, and 15% take five or more.[1] In addition, approximately 20% of adults in the United States use natural products (herbs and other botanicals and enzymes).[2] These numbers have increased significantly over the last decade due to a much higher use of most types of medication. Because almost every drug a patient takes has the potential to cause an adverse effect and an associated drug-induced disease, the likelihood is quite high that a healthcare practitioner will encounter patients with one of these drug-related problems.

Unfortunately, clinicians are often slow to recognize adverse drug reactions and their associated drug-induced diseases. Sometimes they are not recognized at all. Patients' symptoms can easily be confused with those of commonly encountered and naturally occurring disease states. Sometimes an adverse drug effect can be mistaken for an exacerbation of a patient's pre-existing condition. As many as 20% of marketed drugs cause serious adverse effects not identified prior to approval and marketing, and serious adverse events have been reported with 33% of drugs following "fast track" approval by the U.S. Food and Drug Administration (FDA).[3] Despite these difficulties, early detection and correction of drug reactions and drug-induced diseases can help reduce morbidity and mortality and is therefore critically important.

Drug reactions can be divided into four general classes[4]:

- *Type A reactions*—These reactions are predictable, common, and relate to the pharmacological action of the drug. These may include reactions associated with drug toxicity or overdose (e.g., acetaminophen-induced hepatic failure), side effects (e.g., sedation with antihistamines), secondary effects (e.g., diarrhea with oral antibiotics), or drug interactions.
- *Type B reactions*—These reactions are unpredictable, uncommon, and usually not related to the pharmacological actions of the drug. These include allergic reactions as well as those reactions generally described as idiosyncratic (e.g., primaquine-induced hemolytic anemia in a G6PD [glucose-6-phosphate dehydrogenase]-deficient patient). An idiosyncratic reaction is defined as an uncharacteristic, nonimmunological response to a drug that is not related to its pharmacological actions.
- *Type C reactions*—These reactions are associated with long-term drug therapy (e.g., analgesic nephropathy).
- *Type D reactions*—These reactions refer to carcinogenic and teratogenic effects.

About 80% of adverse drug reactions are classified as Type A.[5] Type C and D reactions are delayed in onset and rare compared to Type A and B reactions.

To help ensure that a drug-induced disease is not overlooked in a patient or inappropriately attributed to another cause, clinicians must have a high index of suspicion where drug therapy is concerned. When a patient presents with a new symptom or a symptom that has intensified or changed over time, the clinician must at least entertain the notion that the occurrence might be drug-induced. Every drug a patient is taking or has recently taken should be considered and ruled out as a possible cause. This is easier in some situations and with some drugs and reaction types than others.

PATIENT EVALUATION

Perhaps the most important tool for evaluating a possible drug-induced disease is the medication history. A careful history can yield many clues that will help the clinician rule in or rule out a drug-induced disease. Information that should be collected as part of the medication history is listed in **Table 5-1**. Information may be gathered from many sources including the patient, medication containers, a spouse or caregiver, the patient’s medical records, or another healthcare provider such as the patient’s primary care physician or pharmacist. The accuracy of the medication history depends not only on the accuracy of the source data but also on the skill and knowledge of the healthcare provider who collects the information and puts it all together. Asking the right questions in the right way can elicit information regarding a patient’s medication use that otherwise might be overlooked. **Table 5-2** lists suggestions for obtaining an accurate medication history. Information available to a physician at the time of admission may be inaccurate and could result in an incomplete or inaccurate medication history.[6,7] Due to more extensive knowledge of various drugs and drug products, greater focus on medication therapy issues, and access to more information sources, pharmacists often are able to perform more complete medication histories.[8,9]

Information regarding prescription drugs (including any sample medications, inhalers, creams, ointments, patches, and medications administered in a physician’s office, clinic, or infusion center), over-the-counter (OTC; nonprescription) drugs, vitamins, herbals (nutraceuticals, health supplements), and illicit drugs should be collected. Smoking history and alcohol use should also be documented. The name of each medication, its strength, formulation (tablet, capsule, liquid, extended release), dose, route, and frequency should all be recorded. The objective is to determine how a medication has actually been used rather than how it was prescribed. A precise history of when the medication was started and stopped and when the last dose was taken is critical to the investigation of a possible drug-induced disease. In some cases, it is important to know not only about current medications but also about medications that were taken in the past and recently discontinued. Although some patients are very good historians, it is not always advisable to rely solely on the information patients provide. Discussions with a spouse or caregiver or a phone call to the patient’s pharmacy to check refill history can sometimes yield additional helpful information.

It is also important to collect a careful history of suspected adverse drug events. What did the patient notice, and when did it start? How did the problem progress? Was there a temporal relationship between the onset of symptoms and the addition or discontinuation of any medications and, if so, was the timing of the event similar to that reported previously for a specific drug or drugs for that disease? Has the patient experienced similar reactions in the past? Can the patient provide any insight into what he or she suspects may be causing the problem? Did the patient attempt to self-medicate to treat the problem? If so, what treatment was tried, and was it effective? Do any treatments or activities seem to make the problem better? Does anything seem to make it worse?

Table 5-1 Information That Should Be Included in the

Medication History

Patient information

- Age (date of birth)
- Sex
- Height
- Weight/BMI
- Race

Current prescription medications being taken or used by the patient

- Name of the medication
- Strength
- Formulation (tablet, capsule, extended release, etc.)
- Dose
- Route
- Frequency
- Reason started
- When started
- Date and time of last dose
- Where medication was procured

Prescription medications taken or used in the last 6 months

- Name of the medication
- Strength
- Formulation (tablet, capsule, extended release, etc.)
- Dose
- Route
- Frequency
- When started and stopped
- Reason discontinued
- Where medication was procured

Current nonprescription (OTC) medications (including vitamins, herbal products, health or dietary supplements, energy enhancers or "nutraceuticals")

- Name of the product
- Strength
- Formulation
- Dose
- Route
- Frequency
- Reason started
- When started
- Date and time of last dose
- Where product was procured

Nonprescription (OTC) medications (including vitamins, herbal products, health or dietary supplements, energy enhancers or "nutraceuticals") taken or used in the past 6 months

- Name of the product
- Strength
- Formulation
- Dose
- Route
- Frequency
- When started and stopped
- Reason for discontinuing use
- Where product was procured

Current and/or past use of tobacco

- Type (cigarettes, pipe, cigar, smokeless tobacco, electronic cigarettes)
- Frequency (e.g., number of packs per day)
- Date started
- Last use

Current and/or past use of alcohol

- Type (liquor, wine, beer)
- Amount and frequency
- Date started
- Last use

Current and/or past use of illicit drugs

- Drug name
- Method of administration (oral, inhaled, smoked, injected)
- Frequency
- Date started
- Last use

Financial issues

- Approximate monthly out-of-pocket medication costs
- Financial burden created by medication purchase

Allergies

- Name of medication or type of food causing allergic reaction
- Type of reaction
- Date of reaction
- Treatment and outcome
- Similar reactions to related drugs or similar foods
- Exposure to common drug allergens (penicillin and sulfa-containing compounds)

Adverse drug reactions

- Name of the medication
- Dosage and frequency
- Reason the medication was being taken
- Nature of the reaction experienced
- How the reaction was treated or managed

BMI = body mass index, OTC = over-the-counter.

Table 5-2 Suggestions for Improving the Accuracy of the Medication History

- Carefully review the patient’s medical record and/or other available records before starting the interview to be efficient when questioning and gathering information.
- When possible, set up a special time to do the interview in a private area. The interviewer should not appear rushed and should maintain eye contact and be polite, friendly, and nonjudgmental.
- Use primarily open-ended questions (e.g., “What do you take for back pain?”) rather than closed-ended questions (e.g., “Do you take anything for your back pain?”) during the interview.
- Be nonjudgmental and make sure to not lead the patient into saying what he or she thinks the interviewer wants to hear. The objective is to find out how medications are actually being used and not how the patient was told to use them.
- Remember to ask patients about medications other than those they take orally (e.g., “Do you use eye drops?”). Patients often forget to mention creams, ointments, patches, eye or ear drops, inhalers, and infusions.
- To help stimulate a patient’s memory, ask about medications they take for medical conditions they are known to have (e.g., “What do you take for your glaucoma?”).
- Ask patients about medications prescribed by specialists they may see (e.g., “Do you see an allergist? What medications does he or she prescribe for you?”).
- Ask patients if their physician recently started, stopped, or made any changes to the medications they are taking.
- Call the patients’ community pharmacist to determine an exact medication, dosage strength, directions for use, and adherence (refill history).
- For inquiring about nonprescription medications, additional prompts may include, “What do you take for…”
    - Headache
    - Cold/flu
    - Allergies
    - Sinus
    - Cough
    - Sleeplessness
    - Drowsiness
    - Weight loss/gain
    - Heartburn
    - Stomach upset
    - Gas
    - Constipation
    - Diarrhea
    - Muscle or joint pain
    - Skin problems

A careful physical exam focusing on the organ system(s) involved and the collection of laboratory data can provide objective information helpful in determining whether or not a drug-induced disease is present. Depending on the reaction type and organ system(s) involved, evaluation of kidney function (blood urea nitrogen, serum creatinine, and estimated creatinine clearance), hepatic function (alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, gamma-glutamyl transferase, total and direct bilirubin, total protein, albumin, international normalized ratio), blood counts, serum drug (and, where appropriate, metabolite) concentrations and/or urinalysis may be helpful and necessary. Special laboratory tests (e.g., antinuclear antibodies, histamine metabolites, complement concentration, patch tests) are available and helpful in some situations. Noninvasive procedures (e.g., electrocardiogram, chest x-ray, computed tomography scan) and even invasive procedures (e.g., kidney or lung biopsy) may be required for some patients. Specific elements of the physical exam and laboratory evaluation important in the differential diagnosis of drug-induced diseases are discussed in Chapters 6–58.

The patient's history and physical exam should be carefully reviewed for the presence of risk factors known to be associated with the suspected drug-induced disease. Race, sex, age, genetic and environmental factors, concomitant drug therapy, comorbidities, immune status, alcohol and tobacco use, and a host of other factors may impact patients' relative risk for developing a drug-induced disease. Specific risk factors for the various drug-induced diseases are included in Chapters 6–58.

DIFFERENTIAL DIAGNOSIS

Once subjective and objective information regarding a suspected drug-induced disease has been collected, the known adverse effect profile of each drug to which the patient has been exposed should be evaluated to determine whether or not there is a likely culprit. Evidence of the ability to cause drug-induced diseases is better for some drugs than others, and, even when evidence is totally lacking, it must be remembered that there was a first report for every adverse drug effect and drug-induced disease recognized today.

Authors of chapters in this text have categorized the strength of evidence that a given drug causes a specific drug-induced disease as Level A, B, or C:

- *Level A*—This level indicates evidence of causation from one or more randomized, controlled clinical trials.
- *Level B*—This level indicates evidence of causation derived from nonrandomized clinical trials, prospective observational studies, cohort studies, case-control studies, meta-analyses and/or postmarketing surveillance studies.
- *Level C*—This level indicates there has been one or more published case reports or case series implicating a given drug as the causative agent of a specific drug-induced disease. Although they may not provide proof of causation, case reports are by far the most common evidence available for most drug-induced diseases and are very important to our understanding of these adverse drug events.

Additional B level evidence should become available as more structured approaches to postmarketing surveillance are implemented (see Chapters 1 and 4).

Perhaps the most challenging aspect of evaluating a patient with a suspected drug-induced disease is assessing causation for the observed signs or symptoms. A conference held in Morges, Switzerland in 1981 was an early attempt to bring organization and structure to causation assessment. Conferees agreed on what became called the *9 points of consideration* when attempting to determine if a particular drug was the cause of a suspected adverse event.[10]

The considerations included the following:

1. Whether or not the drug was given prior to the event
2. Whether or not the reaction occurred at the site of application
3. Whether or not the interval following exposure to the drug was compatible with the occurrence of the reaction
4. Whether or not the reaction immediately followed drug exposure and had an acute onset
5. Whether or not the patient suffered the same reaction when rechallenged with the suspected drug
6. Whether or not the reaction improved when the drug was discontinued
7. Whether or not multiple drugs were discontinued simultaneously
8. Whether or not the patient had suffered the same reaction to the drug before
9. Whether or not the observed reaction was known to occur with the suspected causative agent

In the years since the Morges conference, a number of approaches to assess causality have been described.[11-18] The World Health Organization–Uppsala Monitoring Center (WHO–UMC) system (**Table 5-3**) allows users to place suspected reactions into one of six categories (from *unlikely* to *certain*) based on identified characteristics.[19] The Naranjo Scale (**Table 5-4**) assigns point values based on a similar set of findings.[20] There are limitations to the use of these methods. To accumulate points for each question with the Naranjo Scale, for example, the dose of the suspected drug would have to be increased or decreased to see if the reaction worsened or improved, the drug would have to be discontinued to see if the reaction subsided and then readministered to see if the reaction reappeared, and the patient would have to receive a placebo to see if it precipitated a similar reaction. These maneuvers are not always practical, possible, or ethical in clinical practice. As a result, few adverse reactions can be classified as *highly probable* or *doubtful*, and most fall somewhere between these extremes (i.e., *possible* or *probable*). Although none of the published causality assessment tools provides precise and reliable quantitative data, they do provide a structured basis for assessment in a standardized and relatively reproducible format and are used widely, particularly by journals assessing case reports submitted for publication.

Table 5-3 The World Health Organization–Uppsala Monitoring Center (WHO–UMC) System for Classification of Suspected Adverse Drug Reactions[19]

WHO–UMC Classification	Characteristics
C1—Certain	Plausible time; not related to underlying condition, concurrent disease, other drugs or chemicals related pharmacologically Positive dechallenge; positive rechallenge
C2—Probable	Reasonable time; unlikely to be related to concurrent disease, other drugs Positive dechallenge; no rechallenge
C3—Possible	Reasonable time; may be due to concurrent disease, other drug No information on dechallenge
C4—Unlikely	Improbable temporal relationship; other confounding factors such as drugs, chemicals, underlying disease
C5—Conditional/unclassified	Reported as an adverse reaction, but more data are needed for proper assessment
C6—Unassessable/unclassifiable	Report suggesting an adverse reaction but cannot be judged because of insufficient or contradictory information

When it is *possible*, *probable*, or *highly probable* that a medication is causing a drug-induced disease, the clinician must decide whether to continue therapy with that medication or modify the patient's therapeutic regimen. As with all decisions regarding drug therapy, the relative risks and benefits of each course of action must be carefully considered. The substitution of an agent less likely to cause the drug-induced disease may be an option in some cases. When an adverse drug event is known to be dose- or serum concentration-related, reducing the dose of the offending agent or changing the frequency of administration or dosing schedule may be viable options. Although it is not generally a good idea to treat an adverse effect of one drug with a second drug, there are times when this approach is acceptable (e.g., chemotherapy-induced nausea and vomiting). Desensitization is sometimes an option for patients with drug-induced diseases that are immunologically mediated.

Situations in which there is more than one possible culprit drug can create an even greater challenge for clinicians. In some cases, it may be necessary to discontinue all of the possible offending agents and then reinitiate therapy one drug at a time following resolution of the drug-induced disease. In other cases, the WHO–UMC or Naranjo Scale probability rating for each of the possible culprits or the associated level of evidence (e.g., 2 case reports versus 20 case reports versus evidence of causation from one or more randomized, controlled clinical trials) might provide useful clues as to which agent is the most likely offender.

Table 5-4 The Naranjo Scale for Estimating the Probability of Adverse Drug Reactions

Question	**Points**
Are there previous conclusive reports on this reaction? Yes (+1) No (0) Don't know (0)	
Did the adverse event appear after the suspected drug was administered? Yes (+2) No (–1) Don't know (0)	
Did the adverse reaction improve when the drug was discontinued, or a specific antagonist was administered? Yes (+1) No (0) Don't know (0)	
Did the adverse reaction reappear when the drug was readministered? Yes (+2) No (–1) Don't know (0)	
Are there alternative causes (other than the drug) that could on their own have caused the reaction? Yes (–1) No (+2) Don't know (0)	
Did the reaction reappear when a placebo was given? Yes (–1) No (+1) Don't know (0)	
Was the drug detected in the blood (or other fluids) in concentrations known to be toxic? Yes (+1) No (0) Don't know (0)	
Was the reaction more severe when the dose increased, or less severe when dose was decreased? Yes (+1) No (0) Don't know (0)	
Did the patient have a similar reaction to the same or similar drug in any previous exposure? Yes (+1) No (0) Don't know (0)	
Was the adverse event confirmed by any objective evidence? Yes (+1) No (0) Don't know (0)	
Total Points:	
Probability that adverse drug event has occurred: ≥9 highly probable ≥5 probable ≥1 possible 0 doubtful

DOCUMENTING AND REPORTING DRUG-INDUCED DISEASES

PATIENT EDUCATION

Patient education and good documentation are critical to the prevention of a recurrent adverse drug event or drug-induced disease in a given patient. The patient needs to know the nature of the reaction that occurred, the generic name and trade names of the causative agent, the generic name and trade names of any other medications that might be expected to cause similar reactions, and whether or not these agents must be avoided entirely or used only with caution. When patients are warned about potential adverse effects of an entire class of drugs (e.g., angiotensin-converting enzyme inhibitors, sulfa-containing compounds, benzodiazepines), they should be given the generic name and trade names of drugs included in that class. All of this information should be reduced to writing, and the patient should receive a copy to keep with important medical records at home and copies to give to each of their other healthcare providers (e.g., physicians, dentists, nurse clinicians, pharmacists). A narrative description of the adverse event should be included in the patient's medical record and, when hospitalization has occurred, in the discharge summary and in any follow-up correspondence with admitting or referring physicians. Depending on the severity and acuity of the reaction, patients should be advised to obtain and wear a medical alert bracelet.

REPORTING DRUG-INDUCED DISEASES

Proper reporting can also be important in efforts to help prevent drug-induced diseases in others who will be exposed to the drug in the future. Some adverse drug effects and their associated drug-induced diseases have been well documented and are well known to healthcare providers. Because they are well known, these adverse events can sometimes be prevented with careful drug use and/or patient monitoring. Unfortunately, some adverse drug effects and drug-induced diseases have not yet been recognized or characterized. These are unexpected and, therefore, not yet preventable. Identifying and characterizing these events, and therefore increasing the likelihood they can be prevented in the future, is the focus of the FDA's voluntary MedWatch program.[21]

The FDA established MedWatch in 1993 as a method to stimulate voluntary reporting of serious adverse events by healthcare professionals and patients. The system collects spontaneous reports of adverse events involving drugs (prescription and OTC), biologics, devices, and special nutritional products including dietary supplements, medical foods, and infant formulas. Adverse reactions associated with vaccines are reported to the FDA through the Vaccine Adverse Event Reporting System, rather than through MedWatch. A spontaneous report is an observation of an adverse event that is made during direct patient care and subsequently reported either directly to the FDA or indirectly to the FDA through the drug's manufacturer. Observations made during clinical trials are not included as part of this spontaneous reporting system. The MedWatch system is also used to collect information regarding product quality problems, reports of suspected counterfeit products, and reports of medication and device use errors that may have been caused by either product name confusion or confusion resulting from packaging and labeling.

The FDA encourages healthcare providers and patients to use MedWatch to submit reports of serious adverse events. For the purpose of this reporting system, an adverse event is defined as any unfavorable and unintended sign, symptom, or disease temporally associated with the use of a medicinal product, whether or not considered related to the product. The FDA defines serious adverse events as those that are fatal, life-threatening, permanently or significantly disabling, those that require or prolong hospitalization, cause a congenital anomaly, or require intervention to prevent permanent impairment or damage. Notwithstanding these definitions, the FDA encourages health professionals to report any adverse event judged clinically significant. The adverse event does not have to be previously unreported or uncommon. Suspicion that a medical product may be related to a serious event is sufficient reason to submit a report and proof of causality is not necessary.

Reports can be filed online (www.fda.gov/Safety/MedWatch), via a toll-free phone line (1-800-FDA-1088), by fax (1-800-FDA-0178) or by prepaid mail. The core elements of the report include the reporter's name, the suspect drug or device, a narrative report of the adverse event or problem, and patient information (identifier, sex, age, and weight). The FDA holds patient identity information in strict confidence. Reporting does not violate provisions of the Health Insurance Portability and Accountability Act, which specifically permits covered entities (such as pharmacists, physicians, or hospitals) to report adverse events and other information related to the quality, effectiveness, and safety of FDA-regulated products both to the manufacturers and directly to the FDA.

Once received by the FDA, reports of adverse events are entered into a postmarketing surveillance database that can be examined for similar reports and used to develop case series. When a report or a series of reports define a previously unrecognized safety issue, the FDA can order a formal epidemiologic evaluation, require labeling changes including boxed warnings, place restrictions on prescribing or dispensing of the drug or, if necessary, order that the product be withdrawn from the market.

Healthcare providers can obtain information generated through the FDA MedWatch program by accessing their website at www.fda.gov/Safety/MedWatch. Information is also disseminated via email to those who subscribe online and through a large number of professional organizations that partner with the FDA for that purpose.

In 2007, the FDA Amendments Act required the agency to develop an active postmarketing risk identification and analysis program for drugs. In response, the FDA embarked on a program to work with public, academic, and private organizations to develop systems to link and analyze drug safety data from multiple sources. The FDA's Sentinel System was launched in February of 2016, and within the first year allowed the agency to access and analyze electronic medication use and safety data from over 193 million patients. The Sentinel System continues to grow and is intended to complement, but not replace, other surveillance tools such as the MedWatch program.

SUMMARY

Morbidity and mortality associated with drug-induced diseases continue to be a major concern for all healthcare practitioners. Drug-induced diseases may also result in substantial healthcare resource utilization and increased costs. Although some drug-induced diseases are identified during clinical trials and the drug approval process, others are not recognized until long after the drug is marketed and available for routine use. Although all drugs have the potential to cause drug-induced diseases, it is easy to overlook them as a possible cause of a patient's illness. All healthcare providers would be well advised to always ask themselves "Could this be drug-induced?" when confronted with a patient experiencing new or worsening symptoms.

Drug Allergy and Cutaneous Diseases

Lynne M. Sylvia

The terms *drug allergy* and *drug hypersensitivity* are often used synonymously to describe adverse drug reactions mediated by the immune system. According to the International Consensus (ICON) on Drug Allergy, these terms should not be used interchangeably.[1] Drug allergy refers to reactions for which a definite immune mechanism has been proven.[1] The parent drug or its reactive metabolite serves as an antigen, which is subsequently recognized and processed by the immune system, culminating in the production of drug-specific antibodies or sensitized T lymphocytes. The antigen–antibody reaction can target a variety of cells and body tissues, leading to organ-specific or more generalized systemic adverse events. The expert panel on drug allergy recommends that the term *drug hypersensitivity reaction* be used for adverse events that clinically resemble allergy but may or may not be mediated by an immune response.[1] Drug hypersensitivity reactions (DHRs) are more heterogeneous in clinical presentation and underlying mechanism. The implicated drug often has the ability via its chemistry or pharmacology to directly stimulate the release or activation of inflammatory mediators from mast cells, basophils, or other body tissues, causing a reaction that is clinically indistinguishable from drug allergy. The term *drug pseudoallergy*, to describe allergic-like reactions, is no longer recommended. A comparison of the features of drug allergy and DHRs is provided in **Table 6-1**.

Cutaneous eruptions, the most common manifestation of drug-induced disease, can result from both immune- and nonimmune-mediated mechanisms (e.g., pharmacologic effects, idiosyncratic). Therefore, drug-induced skin eruptions and systemic skin diseases are discussed in a separate section of this chapter. Allergic-mediated urticaria, angioedema, and the immune complex diseases associated with dermatologic manifestations (serum sickness-like syndrome, vasculitis) will be discussed in the following section.

DRUG ALLERGY AND DHRs

CAUSATIVE AGENTS

A list of the drugs most frequently implicated in drug allergy is provided in **Table 6-2**.[2,4-139] If a particular drug of concern is not included in this table, it should not be assumed that the drug is incapable of eliciting an immune response. Many drugs are not identified as antigenic until well after approval and use in an extended patient population. To determine a drug's potential to serve as an antigen, three drug-related properties should be considered. First, the molecular weight of a drug can influence its antigenicity. Drugs of molecular weight >4,000 Da, such as erythropoietin, insulin, or other polypeptide hormones, are more capable of serving as complete antigens than are low-molecular-weight drugs (<1,000 Da).[140] Biologic agents (e.g., antisera, antithymocyte globulin, intravenous immunoglobulin) also fit into this category of large polypeptides. Second, drugs containing foreign proteins or large polypeptides of nonhuman origin (e.g., streptokinase, beef or pork insulin, chimeric/murine-derived monoclonal antibodies, L-asparaginase) have the ability to serve as complete antigens.[1,140] However, the most common antigenic drugs (e.g., penicillins, sulfonamides) are of low molecular weight (<1,000 Da) and do not contain a foreign protein. These agents possess a third drug-related property related to conferring antigenic potential, which is the ability of the parent drug or its reactive metabolite to bind covalently to a carrier protein in vivo, thereby forming a complete antigen. The term *hapten* is used to describe a drug (or a metabolite) that must bind to a tissue or cell protein to serve as a complete antigen.[1] Identifying a drug's reactive metabolites and the potential of these metabolites to bind to carrier proteins is not readily achieved in premarketing studies; thus, the allergic potential of many low-molecular-weight drugs is not determined until postmarketing.

Table 6-1 Differentiating Features of Allergy Versus Drug

Hypersensitivity Reactions[1-3]

Characteristic	Allergy	Drug Hypersensitivity Reactions
Clinical presentation	Highly variable; ranging from a localized erythematous rash to life-threatening reactions including anaphylaxis, Stevens–Johnson syndrome, and toxic epidermal necrolysis	Highly variable; ranging from infusion-related reactions such as skin flushing to severe reactions mimicking anaphylaxis
Sensitization period	Required; usually ranging from 5 to 21 days after drug initiation	Not required; reaction can occur within seconds to minutes after administration of first dose
Antibody involvement	Yes; IgE, IgG, IgM, or sensitized T lymphocytes	Not proven; may or may not be mediated by an immune response
Mechanism	Drug can serve as a complete antigen or hapten (parent drug or metabolite) or may bind to T-cell receptor to stimulate immune response	Based on its chemical or pharmacologic properties, drug stimulates release or activation of inflammatory mediators
Risk factors	Highly variable; dependent on drug or patient (host)	Highly variable; dependent on drug or patient (host)
Pretreatment	Not routinely recommended; yield of antibody produced by any given antigenic drug too unpredictable to fully antagonize via pretreatment	Pretreatment regimens are recommended for some drugs; may be recommended to block effects of drug on effector pathways
Treatment	Dependent on signs and symptoms of reaction; includes antihistamines, epinephrine, and corticosteroids	Dependent on signs and symptoms of reaction; may include dose reduction, alteration in rate of infusion, or treatment with antihistamines, epinephrine, or corticosteroids

IgE = immunoglobulin E, IgG = immunoglobulin G, IgM = immunoglobulin M.

Table 6-2 Agents Implicated in Allergic Drug Reactions

Drug	Incidence	Level of Evidence[a]
ANAPHYLAXIS, URTICARIA, ANGIOEDEMA, AND BRONCHOSPASM		
Amphotericin B[4,5]	NK	C
Aprotinin[6]	NK	C

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Drugs that are commonly associated with DHRs are listed in **Table 6-3**.[141-161] A drug's ability to cause a nonimmune DHR can often be assessed by a review of the drug's chemical and/or pharmacologic properties. Classic examples are anaphylactoid reactions to radiocontrast media, opioid-induced urticaria or generalized pruritus, red man syndrome with vancomycin, and nonsteroidal anti-inflammatory drug (NSAID)-induced asthma or angioedema.

When reviewing Tables 6-2 and 6-3, it should be noted that some drugs are listed as causing both allergy and DHRs. For example, vancomycin-induced red man syndrome is thought to be a nonimmune DHR, whereas vancomycin-associated blood dyscrasias and anaphylaxis are attributed to more rare allergic reactions.[67,127,128] Captopril, ciprofloxacin, and protamine have also been reported to cause both true allergy and nonimmune DHRs. Intravenous immunoglobulin G (IVIG) is most commonly associated with infusion-related reactions such as fever and arthralgias. However, IVIG can also cause an IgE-mediated reaction in patients with selective IgA deficiency.[3] In situations in which a drug can cause both types of reactions, it is often difficult to distinguish between allergy and a nonimmune DHR. Most importantly, the signs, symptoms, and severity of the reaction, rather than its mechanism, should drive clinicians' decision-making.

EPIDEMIOLOGY

Collectively, drug allergy, intolerance, and nonimmune DHRs have been estimated to comprise 25% of all adverse drug events.[2] Drug allergy is considered to be relatively rare, representing 6–10% of all adverse drug reactions.[2,162] In 2002, Hunziker et al.[163] provided an analysis of 12,785 adverse drug reactions of probable or definite association occurring in inpatients between 1974 and 1993. Drug allergy and nonimmune DHRs accounted for 13% of the adverse drug reactions. Differentiation between allergy and nonimmune DHRs as the cause of the adverse event could not be achieved because of the lack of valid skin testing or other in vitro testing methods to determine the presence of drug-specific antibodies.[163]

The epidemiology of anaphylaxis, including drug-induced anaphylaxis, has been re-evaluated by a working group composed of experts in allergy and immunology.[164] The expert panel estimated the frequency of anaphylaxis in 2006 to be 50–2,000 episodes per 100,000 persons, or a lifetime prevalence of 0.05–2%.[164] More recent estimates suggest that the prevalence is increasing, particularly in younger age groups and in patients treated with biologic agents. Neugut et al.[165] reported that the most serious cases of drug-induced anaphylaxis have been associated with the use of penicillin and radiocontrast media. Penicillin is recognized as the most common cause of anaphylaxis and is estimated to account for approximately 75% of fatal cases in the United States annually.[2] Nonfatal anaphylaxis attributed to penicillin has been reported in 0.7–10% of the general population, whereas fatal cases occur in 0.002% of the general population.[165] Non-IgE-mediated anaphylaxis (i.e., anaphylactoid reactions) associated with radiocontrast media have occurred in 0.22–1% of patients, particularly in those receiving an agent with high osmolarity.[165]

Table 6-3 Agents Implicated in Nonimmune Drug Hypersensitivity Reactions

Drug	Incidence	Level of Evidence[a]
Adrenocorticotropic hormone	NK	C
Angiotensin-converting enzyme inhibitors[2,141-142]	0.1–0.2%	B
Angiotensin receptor blockers[143-146]	0.11%	B
Acetylsalicylic acid (aspirin)[10,11]	NK	C
Ciprofloxacin[147-149]	NK	C
Corticosteroids[150]	NK	C
Cremophor (polyethoxyethylated castor oil)-containing products[7,9]	NK	C
Enoxaparin[151]	NK	C
Infliximab[152-153]	NK	C

Angioedema is estimated to occur in 0.1–1.2% of patients treated with angiotensin-converting-enzyme (ACE) inhibitors.[141] However, as many as 25–38% of cases of angioedema presenting to the emergency department (ED) have been attributed to ACE inhibitor therapy.[166,167] In an 8-year retrospective study, 12 of 49 patients (24.5%) presenting to the ED with angioedema reported concomitant therapy with an ACE inhibitor.[166] A second retrospective case-control study revealed an association between ACE inhibitors and angioedema in 15 of 40 patients (38%) presenting to the ED.[167] Compared with a control group of patients without angioedema, patients presenting to the ED with angioedema were 5 times more likely to be taking an ACE inhibitor (OR 5.1, 95% CI 2.03–12.89).[167]

The incidences of allergy and nonimmune DHRs associated with the majority of implicated drugs are unknown. The estimated incidences of allergy and nonimmune DHRs associated with some implicated drugs are presented in Tables 6-2 and 6-3.

MECHANISMS

DRUG ALLERGY

The exact mechanisms by which drugs serve as allergens and elicit immune responses are not well understood. Gaps in our understanding of these mechanisms can be attributed, in part, to the lack of a validated animal model of drug allergy.[168] Another influencing factor is the difficulty in identifying and isolating the antigenic components and metabolites of potential drug allergens. Although much is unknown about the mechanisms by which drugs cause allergy, it is known that a single drug, such as penicillin, can cause a variety of allergic reactions via different mechanisms.[168] At least two theories—the prohapten/hapten concept and the p-i concept—have been described to explain the manner in which drugs stimulate the immune response. Each theory will be discussed separately.

PROHAPTEN/HAPTEN THEORY

In this theory, a number of complex stages appear to be involved in the generation of an immune response to a drug. These stages include the following:

1. Formation of a complete antigen
2. Processing of the complete antigen by antigen-presenting cells
3. Recognition of the antigenic determinant by T lymphocytes
4. Generation of a drug-specific antibody or sensitized T cells
5. Elicitation of a clinical immune response

STAGE 1: FORMATION OF A COMPLETE ANTIGEN

Most drugs that serve as immunogens are low-molecular-weight compounds (<1,000 Da) and are too small to initiate an immune response alone. To be recognized by the immune system, these drugs must bind, usually covalently, to a high-molecular-weight carrier protein, thereby forming a complete antigen. Haptens are drugs that bind to tissue or plasma proteins to form a complete antigen.[1,169] The parent drug rarely has the ability to bind to tissue or cell proteins. For most low-molecular-weight drug immunogens, the hapten is a reactive metabolite of the parent drug, formed via metabolism in the liver, skin keratinocytes, or white blood cells.[168,170] As an example, sulfamethoxazole is well recognized as a highly allergenic compound, but a reactive metabolite, the nitroso-sulfamethoxazole derivative, not the parent compound, serves as the primary hapten.[171] In this regard, the parent drug, sulfamethoxazole, would be considered a prohapten.

STAGE 2: PROCESSING OF THE COMPLETE ANTIGEN BY ANTIGEN-PRESENTING CELLS

Once a hapten–protein conjugate has been formed, it must undergo antigen processing. This crucial stage involves recognition of the complete antigen by antigen-presenting cells (APCs). A number of cells serve as APCs, including macrophages, dendritic cells, cutaneous Langerhans cells, and B lymphocytes.[168-

[170] With many drug immunogens, the complete antigen is believed to diffuse across the cell membrane of the APC and be internalized into the lysosomes of the APC. Metabolism by proteolytic enzymes in the lysosomes allows for breakdown of the complete antigen to a smaller, hapten–peptide fragment.[172] The last step in this stage of processing is the binding of the hapten–peptide fragment with major histocompatibility complex (MHC) class I or II molecules synthesized by the APC.[1,168,169] Expression of the hapten–MHC complex on the surface of the APC allows recognition by T lymphocytes and further progression of the immune reaction.

STAGE 3: RECOGNITION OF THE ANTIGENIC DETERMINANT BY T LYMPHOCYTES

The manner in which T-helper cells recognize the hapten–MHC complex is not fully understood. It is theorized that three signals must occur for T-helper cells to become activated.[168,170,173,174] The first signal is completed by the interaction of the hapten–MHC complex with an antigen receptor on the surface of the T-helper cell. The second signal is believed to involve an interaction between specific receptors on the APC and the T-helper cell, resulting in the release of cytokines (cell messengers), such as interleukin (IL)-1 or IL-6. If this second signal does not occur, it is believed that the T-helper cells lose their responsiveness to the antigen, and the immune reaction ceases to progress.[168,174] Thus, some patients may process a drug allergen but the immune reaction may be blunted at this stage or at other stages in the process. The third signal involves activation of the CD4+ T lymphocytes with the release of specific cytokines from these activated T lymphocytes. Depending on the cytokines released, the T lymphocytes differentiate into either T-helper type 1 (Th1) or T-helper type 2 (Th2) cells.[173] Differentiation of the T-helper lymphocyte is an important step in the determination of the type of immune reaction to a specific drug allergen. Genetic factors are believed to influence T-helper-cell phenotyping in addition to influencing the type of cytokines released from activated T-helper cells. Dominance of cytokines IL-4 and IL-13 lead to the production of Th2 cells, whereas secretion of IL-2 and interferon β favors the production of Th1 cells.[175]

STAGE 4: GENERATION OF A DRUG-SPECIFIC ANTIBODY OR SENSITIZED T CELLS

Immune responses to a drug can lead to the generation of an antibody (humoral immune response) or sensitized T cells (cellular or delayed immune response). If a patient’s response to an allergen is mediated by Th2 cells, a humoral response occurs with IgE, IgG, or IgM as the responding antibody. Th2 cells have the ability to secrete a number of cytokines, primarily IL-4 and IL-13, which stimulate the production of IgE from plasma cells. Th2 cells also secrete IL-5, which activates eosinophils, and IL-3 and IL-10, which are involved in mast cell differentiation.[174] Patients who have a Th1-dominant response to a drug are more likely to generate a cellular immune response with the production of drug-specific sensitized T lymphocytes.[2] At this stage of the immune process, memory cells (either T or B lymphocytes) are also produced to retain memory for the drug allergen. Memory cells allow for a faster onset of an immune reaction upon re-exposure to the antigen.

STAGE 5: ELICITATION OF A CLINICAL IMMUNE RESPONSE

Completion of stages 1 through 4 may not occur until days 5 to 21 of continued drug therapy. This period of sensitization explains the latency in the clinical presentation of the immune reaction. It is also important to consider that some patients may generate an antibody response to a drug allergen, but the event will not progress to a clinical reaction. For example, approximately 40% of patients treated with penicillin for at least 10 days produce drug-specific IgG without manifesting a hypersensitivity response.[2]

The p-i concept: A nonhapten pathway has also been described to explain drug allergy.[1,169,172] Some low-molecular-weight drugs may cause an immune response by “pharmacologically interacting with immune receptors.”[1,172] Known as the p-i concept, these drugs do not require binding to a carrier protein or processing by APCs. This theory suggests that drugs bind directly to T-cell receptors in a reversible manner, similar to a ligand binding to a receptor. It is not known whether the drug first binds to the MHC molecule on the APC to signal T-cell activation or whether it directly binds to the T-cell receptor, stimulating the T-cell response. This concept appears most applicable to the initiation of delayed T-cell mediated-reactions, as opposed to humoral reactions.[1,172]

Mechanism-based classification of drug allergy: Since 1968, the Gell and Coombs[176] classification has been used to differentiate allergic drug reactions based on their mechanism and clinical presentation. Using this classification system, allergic reactions are described as types I through IV. It is important to consider that not all allergic drug reactions can be described using this classification. For example, some drug allergies exhibit features of more than one type (e.g., drug rash with eosinophilia and systemic symptoms [DRESS]). In addition, some allergies are mediated by antibodies not included in the classification (e.g., autoantibodies associated with procainamide-induced syndrome resembling systemic lupus erythematosus). The classification system was developed before our understanding of the varied roles of T cells in the immune response. As such, the original classification system has been adapted in **Table 6-4** to better represent our current understanding of drug allergy.[1,2,176,177]

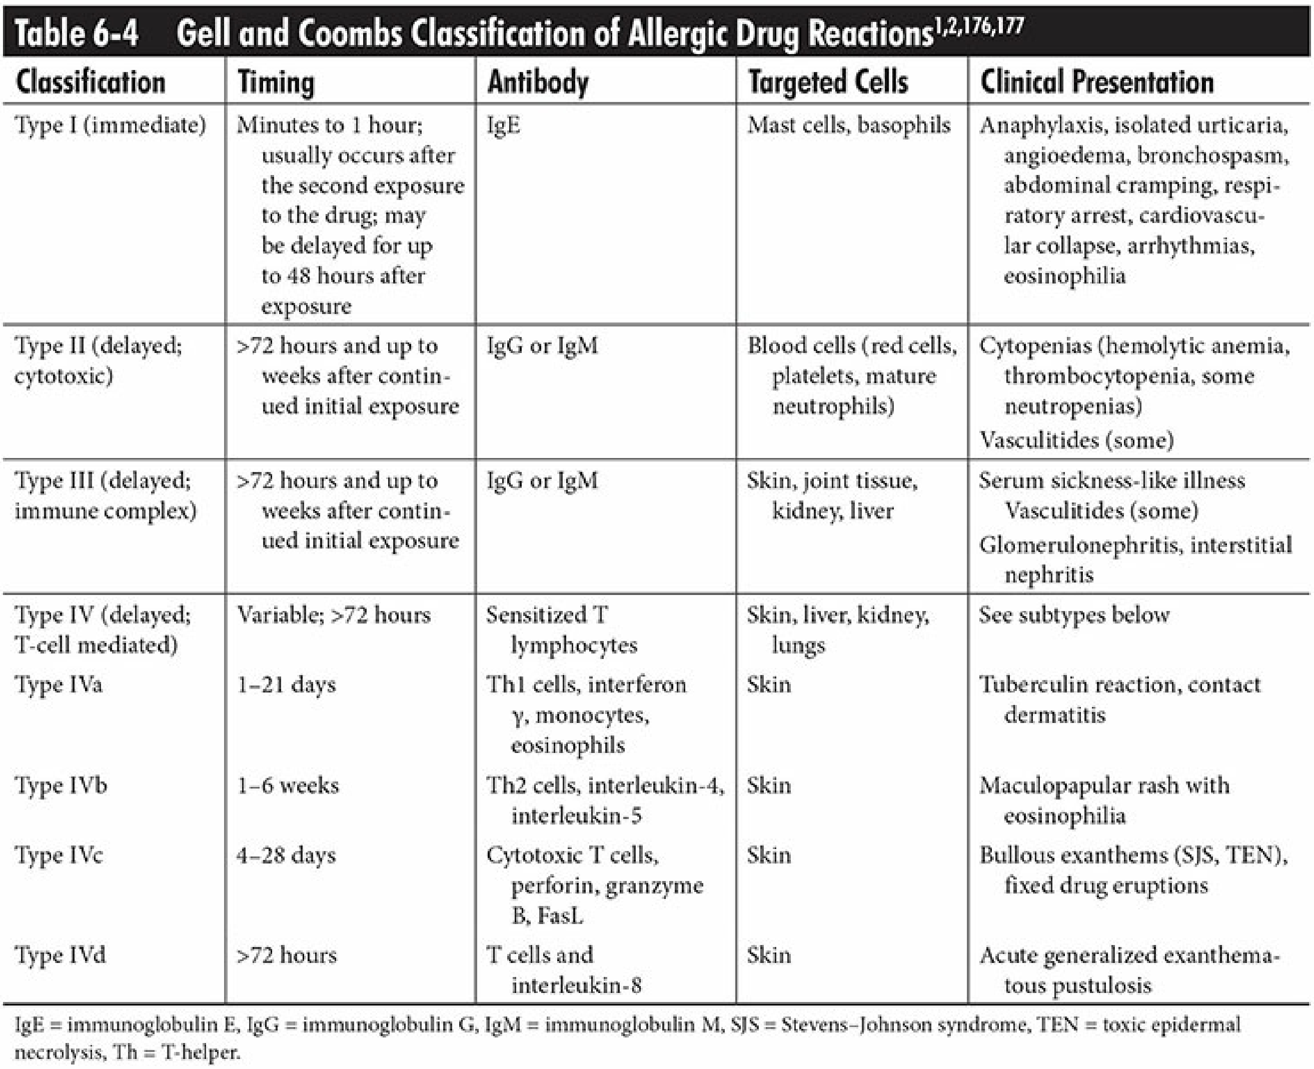

Table 6-4 Gell and Coombs Classification of Allergic Drug Reactions[1,2,176,177]

Classification	Timing	Antibody	Targeted Cells	Clinical Presentation
Type I (immediate)	Minutes to 1 hour; usually occurs after the second exposure to the drug; may be delayed for up to 48 hours after exposure	IgE	Mast cells, basophils	Anaphylaxis, isolated urticaria, angioedema, bronchospasm, abdominal cramping, respiratory arrest, cardiovascular collapse, arrhythmias, eosinophilia
Type II (delayed; cytotoxic)	>72 hours and up to weeks after continued initial exposure	IgG or IgM	Blood cells (red cells, platelets, mature neutrophils)	Cytopenias (hemolytic anemia, thrombocytopenia, some neutropenias) Vasculitides (some)
Type III (delayed; immune complex)	>72 hours and up to weeks after continued initial exposure	IgG or IgM	Skin, joint tissue, kidney, liver	Serum sickness-like illness Vasculitides (some) Glomerulonephritis, interstitial nephritis
Type IV (delayed; T-cell mediated)	Variable; >72 hours	Sensitized T lymphocytes	Skin, liver, kidney, lungs	See subtypes below
Type IVa	1–21 days	Th1 cells, interferon γ, monocytes, eosinophils	Skin	Tuberculin reaction, contact dermatitis
Type IVb	1–6 weeks	Th2 cells, interleukin-4, interleukin-5	Skin	Maculopapular rash with eosinophilia
Type IVc	4–28 days	Cytotoxic T cells, perforin, granzyme B, FasL	Skin	Bullous exanthems (SJS, TEN), fixed drug eruptions
Type IVd	>72 hours	T cells and interleukin-8	Skin	Acute generalized exanthematous pustulosis

IgE = immunoglobulin E, IgG = immunoglobulin G, IgM = immunoglobulin M, SJS = Stevens–Johnson syndrome, TEN = toxic epidermal necrolysis, Th = T-helper.

It is currently recommended that drug allergies be classified as immediate or nonimmediate based on the onset of the reaction.[1,169] According to the ICON expert panel, immediate reactions are those that culminate in the production of an IgE-mediated response.[1] These reactions typically present as angioedema, bronchospasm, or anaphylaxis and usually occur within 1 hour after first re-exposure to the immunogenic drug. Nonimmediate or delayed drug allergies constitute a broader category of events including maculopapular exanthems, delayed urticaria, immune-mediated blood disorders, and serum sickness reactions. Nonimmediate events are typically mediated by activated T cells and occur at least 1 hour after initial drug exposure and up to weeks or months after initial exposure.[1,169] This classification system, as noted by the expert panel, has limitations because the presence of immune cofactors (e.g., viruses) and the route of drug administration may influence the onset or progression of the immune reaction.[1]

If a patient generates IgE as the responding antibody to a drug allergen, the event is classified as an immediate type I reaction. IgE is commonly referred to as a homocytotropic antibody because of its strong affinity for the Fc receptors on mast cells and basophils.[140] IgE avidly binds to basophils in the blood and mast cells located in the skin and respiratory and gastrointestinal tracts and the connective tissue surrounding the blood vessels.[178] When a patient is re-exposed to the allergenic drug, cross-linking occurs between the hapten–protein complex and IgE bound to the surface of mast cells, basophils, or both. Cross-linking between the drug and two molecules of IgE causes an influx of calcium ions that triggers degranulation of the mast cells and basophils.[178] The end result is the extracellular release of a number of preformed inflammatory mediators such as histamine, heparin, and proteases. Influx of calcium also activates phospholipase A_2 and stimulates the release of arachidonic acids, which can be bio-transformed into a number of secondary mediators, including leukotrienes, prostaglandins, and platelet-activating factor.[164] The cytokine known as tumor necrosis factor α (TNFα) has also been implicated as a mediator. Collectively, these mediators of anaphylaxis can cause increased vascular permeability, a wheal-and-flare reaction, smooth-muscle contraction resulting in bronchospasm, nausea, vomiting, recruitment of inflammatory cells, activation of vagal pathways, decreased coronary blood flow, and delayed atrioventricular conduction.[179,180]

Nonimmediate type II cytotoxic reactions are usually mediated by IgG or IgM. During these reactions, the drug hapten typically binds to a cell-surface protein in the membrane of a blood cell (e.g., red cell, platelet, neutrophil).[113,114] A complexation reaction between the responding antibody (IgG or IgM) and the drug hapten bound to the surface protein leads to destruction of the affected cells (i.e., hemolysis, thrombocytopenia, neutropenia). Cell-bound antibody can also activate complement, a series of 25 plasma proteins that, when activated, assist in cell lysis.[113,114,175] Activated complement proteins possess a variety of properties, including the ability to degranulate mast cells (C3a, C5a), the ability to form a membrane attack complex (C5a and C9a), and the ability to stimulate opsonization to amplify the immune response.[175]

Nonimmediate type III reactions, commonly referred to as immune complex reactions, are usually mediated by IgG. During these events, the drug hapten typically forms a complete antigen by binding covalently with an amino acid component (such as the lysine or cysteine residues) of a plasma protein. The hapten–protein complex then stimulates the production of IgG. Binding between IgG and the circulating complete antigen results in the formation of immune complexes, which often circulate throughout the bloodstream and activate the complement cascade before depositing on targeted cells or tissues.[178] Complement-mediated migration of phagocytes and the release of pyrogens manifests as a fluid phase or serum sickness-like reaction consisting of fever, malaise, and lymphadenopathy. Activation of complement proteins C3a and C5a can also result in degranulation of mast cells with the release of histamine. Eventually, the immune complex may deposit in a variety of tissues, including the walls of blood vessels, glomerular cells, joint tissue, alveoli, and cells in the skin. After deposition on the targeted tissue, the immune complex, with the assistance of complement, mediates cell destruction.

Nonimmediate type IV reactions are subclassified as types IVa through IVd based on the responding T cell, effector mechanism, and clinical manifestations (Table 6-4). On exposure to the antigen, a specific subtype of T cell (e.g., Th1 cell, Th2 cell, cytotoxic T cell) orchestrates an inflammatory response through secretion of specific cytokines (IL-4, IL-5).[1,181] Type IV reactions involve a wide range of clinical events including contact dermatitis from a topically applied medication to more serious dermatologic events such as pustular and bullous exanthems. A complete review of the mechanisms by which drugs cause type IV reactions has been published.[181]

MECHANISMS OF DRUG HYPERSENSITIVITY REACTIONS

DHRs can also be classified as immediate or nonimmediate based on the timing of the event.[1] Drugs cause nonimmune DHRs by a number of mechanisms, including (1) direct stimulation of mast cells resulting in the release of histamine (e.g., opioids, polymyxin, protamine, diamines such as pentamidine, polyethoxylated castor oil), (2) nonimmunologic activation of the complement cascade (e.g., radiocontrast media, protamine), and (3) alteration of the metabolism or production of inflammatory mediators (e.g., ACE inhibitors, aspirin, and NSAIDs).[1,169] The direct stimulatory effects of drugs on mast cells appear to be dose-related and tend to predominate on mast cells in the skin. Ciprofloxacin, vancomycin, and muscle relaxants such as succinylcholine and opiates (e.g., codeine, morphine) have been shown to elicit urticarial reactions in normal skin at concentrations of ≥100 mcg/mL.[182] The mechanism by which the ACE inhibitors cause angioedema is not completely understood; however, inhibition of the breakdown of bradykinin and substance P may partially explain this adverse event. ACE, a nonspecific dipeptidase enzyme, not only converts angiotensin I to angiotensin II but is also involved in the inactivation of bradykinin, substance P, and neurokinin A.[141] Elevations in plasma concentrations of bradykinin and substance P can lead to inflammation, increased vascular permeability, and vasodilation. Aspirin-induced asthma, also known as aspirin-exacerbated respiratory disease, is believed to result from an imbalance between the production of prostaglandins and leukotrienes from arachidonic acids.[183] Inhibition of cyclooxygenase-1 (COX-1) leads to decreased production of prostaglandin E_2, a modulating prostaglandin in bronchial tissue, and an increased propensity for arachidonic acids to be synthesized via the lipoxy–genase pathway. Increased production of leukotrienes C4, D4, and E4 is associated with smooth-muscle contraction manifesting as bronchospasm, inflammation, and increased mucus production.[183]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The signs and symptoms of a number of specific allergic syndromes are provided in **Table 6-5**. The clinical presentation of drug allergy is highly variable and dependent on the responding antibody and the targeted tissues. Allergy may manifest as anaphylaxis; angioedema; urticaria; immune-complex diseases manifesting as a serum sickness-like illness, lupus-like reaction, hypersensitivity vasculitis, or DRESS; and mucocutaneous syndromes such as Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN). In addition, allergic drug reactions may be the cause of disorders of the blood, kidney, liver, and pulmonary system. Conditions to consider in the differential diagnoses of these syndromes are listed in **Table 6-6**. The mucocutaneous syndromes and DRESS are discussed in the section Cutaneous Diseases.

Anaphylaxis, the most severe form of an immediate type I reaction, constitutes a medical emergency. The onset of anaphylaxis is usually within minutes to 2 hours after exposure to the causative drug.[184] In rare cases, the onset can be delayed for up to 48 hours after exposure. A consensus panel on allergy has defined anaphylaxis as highly likely when one of the following scenarios is present[184]:

1. Acute onset of a reaction (minutes to several hours) that involves the skin (mucosal tissue) and the respiratory tract and/or a decrease in blood pressure
2. The rapid onset of a reaction after exposure to a likely allergen that involves two organ systems (respiratory tract, skin, decrease in blood pressure, and/or persistent gastrointestinal symptoms)
3. A decrease in blood pressure alone after exposure to a known allergen

An elevated serum tryptase concentration is indicative of the release of stored mediators from mast cells. Concentrations of tryptase, an enzyme that is stored in the secretory granules of the mast cell, become elevated in the serum within 1–2 hours after the onset of anaphylaxis and persist for as long as 6 hours after the event.[164,184] β-tryptase is released only during episodes of mast cell degranulation, whereas concentrations of α-tryptase are elevated in patients with a large mast cell burden (e.g., mastocytosis).[184] Anaphylaxis is most suggestive when the ratio of total (α + β) tryptase to β-tryptase is ≤ 10.[184] Serum platelet-activating factor may also be a biomarker of anaphylaxis.[185] A late phase of anaphylaxis, characterized by erythema, edema, and excess mucus production with mucus plug formation, occurs 8–12 hours after the initial attack and can last for up to 32 hours.[184] The late-phase reaction is attributed to the effects of leukotrienes, such as leukotriene B4, which stimulate migration of macrophages to the sites of tissue damage.[179,180]

Urticaria with pruritis, a common manifestation of anaphylaxis, can also occur as a sole manifestation of an immediate type I reaction. On subsequent exposure to the causative agent, urticaria may progress to include anaphylaxis. Drug-induced angioedema can also occur as a sole manifestation of allergy, or it can occur with urticaria or as part of an anaphylactic event.[186] Angioedema, also known as giant urticaria or angioneurotic edema, presents as nonpitting edema that extends beyond the epidermis to involve the deep dermis, mucous membranes, and subcutaneous tissues.[186] Angioedema secondary to ACE inhibitors is typically confined to the head and neck, presenting as localized swelling of the face (tongue, lips, and eyelids) with edema of the mucous membranes of the mouth, throat, and nose.[141,142] Rarely, the edematous reaction can extend to the gastrointestinal tract, hands, feet, and genitalia.

Table 6-5 Signs and Symptoms Associated with Drug-Induced Allergic Syndromes

Anaphylaxis[2,179,180,184]

- Diffuse urticaria
- Facial flushing
- Angioedema
- Bronchospasm (wheezing, chest tightness, hoarseness)
- Laryngeal edema
- Stridor
- Hypotension
- Cardiac arrhythmias (atrial or ventricular)
- Nausea, vomiting, abdominal cramping, diarrhea
- Lightheadedness, feeling of impending doom
- Eosinophilia
- Elevated tryptase concentrations

Urticaria[285,286]

- Asymmetric, circumscribed erythematous (pink) papular lesions of variable shape ranging from small to geographic in size; lesions have raised borders and areas of central clearing
- Pruritus
- May be associated with angioedema
- May be associated with eosinophilia

Angioedema[184,285,286]

- Asymmetric, nonpitting edema of the face (tongue, lips, eyelids)
- Periorbital edema

- Laryngeal edema
- Tingling of the lips
- Hoarseness, difficulty speaking
- Difficulty swallowing
- Diarrhea, nausea, abdominal pain (if visceral involvement)
- Edema of the extremities, genitalia

Allergic-mediated blood disorders[113,114]

- Hemolytic anemia with positive direct or indirect Coombs test
- Thrombocytopenia, with peripheral count <100,000 mm^3 Granulocytopenia (agranulocytosis, neutropenia)
- Decreased concentrations of C3, C4
- Evidence of antiplatelet or antineutrophil antibodies

Serum sickness or serum sickness-like reaction[69]

- Fever and malaise
- Skin rash—urticaria, maculopapular rash or mixed presentation of urticarial plaques and maculopapular rash usually starting on the extremities (hands, fingers, toes)
- Arthralgias
- Lymphadenopathy
- Glomerulonephritis
- Elevated erythrocyte sedimentation rate (nonspecific marker)
- Reduced concentrations of C4 and C3; possible elevations in C3a

Vasculitis[86,88,188]

- Skin manifestations—purpura, maculopapular rash, hemorrhagic blisters; skin biopsy revealing leukocytoclastic vasculitis with fibrinoid necrosis and lymphocytic infiltrate
- General—fever, nausea, abdominal pain, polyarthritis, joint swelling
- Kidney—urinalysis revealing proteinuria, granular casts, and red cells; kidney biopsy may reveal deposition of IgG, IgM, or activated complement (C3)
- Pulmonary—hemoptysis, wheezing, pleuritic pain, presence of infiltrate on chest x-ray
- Sore throat, hoarseness
- Synovitis
- Elevated erythrocyte sedimentation rate, presence of antinuclear antibodies or antineutrophilic cytoplasmic autoantibodies

IgG = immunoglobulin G, IgM = immunoglobulin M.

The clinical presentation of drug-induced allergic blood disorders is included in Table 6-5. Depending on the causative drug, the patient may present with hemolytic anemia, thrombocytopenia, or granulocytopenia.[113,114] These peripherally mediated blood disorders typically occur within 5–21 days after drug initiation.[113,114] The affected blood cell counts decline rapidly, compared with the relatively slow decline in the counts observed with bone-marrow-mediated blood disorders. In some patients, drug-specific antibodies (IgM or IgG) and reduced serum concentrations of C3 and C4 can be observed.[113,114]

Table 6-6 Conditions to Consider in the Differential Diagnosis of

Drug Allergy

Anaphylaxis[179,180,184]

- Asthma
- Carcinoid syndrome
- Cardiogenic shock
- Croup
- Exercise-induced anaphylaxis
- Idiopathic anaphylaxis
- Insect stings or bites
- Latex allergy
- Panic attack
- Septic shock
- Systemic mastocytosis
- Systemic capillary leak syndrome
- Scrombroidosis
- Vasodepressor (vasovagal neurocardiogenic) syncope
- Vocal cord dysfunction syndrome

Angioedema[184,285,286]

- Insect stings or bites
- Food allergy
- Idiopathic or hereditary angioedema
- Hereditary or acquired C1 esterase inhibitor deficiency
- Systemic capillary leak syndrome
- Latex allergy
- Systemic mastocytosis

Urticaria[285,286]

- Cutaneous mastocytosis
- Mastocytosis in association with hematologic disorders (e.g., leukemia)
- Cholinergic urticaria
- Exercise-induced urticaria
- Infection (Epstein–Barr virus; hepatitis A, B, C; gastrointestinal parasites)
- Foods (peanuts, nuts, fish, shellfish, wheat, eggs, milk, soybeans, fruits)
- Food additives (benzoates, sulfites, monosodium glutamate, FD&C [food, drug, and cosmetic] dyes)
- Scrombroidosis
- Occupational exposures (latex, chromates in cement industry, cosmetics, plants)

Serum sickness-like reaction[69]

- Autoimmune disease (rheumatoid arthritis, lupus erythematosus)
- Hepatitis A, B, C
- Hypersensitivity vasculitis
- Infection (aspergillosis, histoplasmosis, coccidioidomycosis, blastomycosis, Epstein–Barr virus, cytomegalovirus)

Hypersensitivity vasculitis[86-88]

- Infection (bacterial endocarditis, hepatitis B or C, occult abscess)
- Rheumatic diseases
- Malignancy (lymphoma, Hodgkin disease, metastatic carcinoma, multiple myeloma)

- Autoimmune disease (rheumatoid arthritis, systemic lupus erythematosus, Wegener granulomatosis)

Hypersensitivity syndrome[188]

- Cutaneous lymphoma

The immune-complex diseases consist of a group of conditions including serum sickness-like disease (SSLD), hypersensitivity vasculitis, and lupus-like reaction. SSLD is a mild and transient form of the serum sickness that originally occurred with the administration of horse serum in the form of diphtheria antitoxin. The predominant feature of an SSLD is a cutaneous eruption that manifests within 5–21 days after drug initiation.[187] Approximately 90% of patients have either an urticarial reaction due to complement-mediated activation of the mast cells (one third of patients) or a maculopapular rash on the abdomen and extremities with possible extension to the palms and soles (two thirds of patients).[69,187,188] The rash is usually preceded by a prodromal phase consisting of fever and malaise, arthralgias, and lymphadenopathy. In rare instances, the reaction can extend to involve the kidney (i.e., glomerulonephritis). SSLD has been reported in association with a number of drugs, including β-lactam antibiotics, bupropion, cefaclor, ciprofloxacin, minocycline, and sulfonamides.[69-76,80-82] Drug-induced SSLD is often described as a mild condition that is self-limiting after discontinuation of the causative agent. However, in some cases, it progresses to a more serious vasculitis. Any evidence of mucous membrane involvement (i.e., mucocutaneous lesions of the mouth, genitalia, nares) may suggest the development of a more progressive condition, such as SJS.

Drug-induced vasculitides are associated with acute inflammatory and necrotic lesions of the arteries, arterioles, venules, and capillaries. Consistent with other immune-complex diseases, an initial prodromal period is noted within 1–3 weeks after drug initiation and usually consists of fever, arthralgias, and sore throat.[86,188] Cutaneous vasculitis, described as either a purpuric or maculopapular rash of the lower extremities, is the most common presenting manifestation.[87] The purpuric lesions can progress to necrotic ulcerations, and the vasculitic process can extend to include the kidneys, lungs, nasal mucosa, and ears. A number of drugs, such as propylthiouracil, hydralazine, minocycline, phenytoin, and allopurinol, can induce vasculitis through the production of antineutrophil cytoplasmic autoantibodies.[86] Other terms used to describe this condition include leukocytoclastic vasculitis, polyarteritis nodosa, and Churg–Strauss syndrome.

RISK FACTORS

The rarity of drug allergy suggests a reliance on contributory or predisposing factors. Risk factors for drug allergies have been categorized as either drug-related or patient (host)-related. Many extensive reviews have been published describing predisposing factors for both the induction of an immune response to a drug and the elicitation of an allergic drug reaction.[1,182,189,190] However, debate continues as to the influence of these factors on the risk of reactivity. Most risk factors have been identified through small-scale studies and indirect clinical observations. In addition, the majority of the risk assessments have been determined from the study of penicillin. At present, it is not known whether risk factors associated with the penicillins can be extrapolated with confidence to other antigenic drugs. Proposed risk factors for drug allergy are listed in **Table 6-7**. In addition, risk factors associated with specific drugs (e.g., the penicillins, sulfonamides, radiocontrast media) are identified.

Table 6-7 Risk Factors for Allergic and Nonimmune Drug Hypersensitivity Reactions

Allergic reactions

Drug-related factors[182,189,190]

- Chemical properties (molecular weight, polypeptide composition, foreign protein)
- Dose and duration of therapy
- Frequency of treatment courses

Coexisting conditions

- Active infection with Epstein–Barr virus (aminopenicillins)[201]
- Active infection with human immunodeficiency virus (sulfonamides, dapsone, penicillins, ciprofloxacin, phenytoin)[203]
- Cystic fibrosis (β-lactams)[206-208]
- HHV-6 (DRESS)[204,205]

Genetic factors

- HLA B*5701 (abacavir)[193]
- HLA-B*5801 (allopurinol)[335]
- HLA-B*1502 (carbamazepine, phenytoin, fosphenytoin)[355,356]
- HLA-*DRA* (amoxicillin, penicillins)[196]
- CYP2C9*3 (phenytoin)[358]
- HLA-B*13:01 (dapsone)[108]

Patient history

- History of a previous reaction to the specific agent

Pre-existing IgE antibodies against galactose-α-1,3-galactose[24,25]

- Cetuximab

Nonimmune drug hypersensitivity reactions

Drug-related factors[2,3]

- Dose (vancomycin, opiates)
- Infusion rate (vancomycin, paclitaxel)

Patient factors[2,3]

- Female sex (radiocontrast media)[210]
- Atopy (radiocontrast media, aspirin)[211,216]
- Asthma (radiocontrast media, aspirin)[10,11,215]
- Race (angiotensin-converting enzyme inhibitors)[213,214]

Concomitant drug therapy

- β-blockers (radiocontrast media)[21,212]

DRESS = drug rash with eosinophilia and systemic symptoms, HHV-6 = human herpesvirus 6, HLA = human leukocytic antigen.

The three most commonly described drug-related risk factors for an allergic reaction are increased molecular size (molecular weight ≥4,000 Da), chemical composition consisting of proteins or polypeptides, and the ability of the drug or its reactive metabolite to bind covalently to a carrier protein.[189] The presence of proteins of nonhuman origin (e.g., chimeric monoclonal antibodies containing murine-based components, pork insulin, streptokinase) or the inclusion of antigenic excipients (e.g., FD&C dyes, peanut oil, soybean emulsion, sulfites) also increase the risk of drug reactivity. Other proposed drug-related factors include route of drug administration, dose, and frequency of administration. Sensitization to a drug can occur via any route of administration, and allergic reactions have been reported in association with all routes.[140,182] However, once a patient has been sensitized to a drug, subsequent administration of that drug by the parenteral route has been associated with increased severity of an allergic drug reaction.[190] This observation is largely explained by the higher rate of drug delivery with the parenteral route versus other routes of administration, particularly the oral route.[189] Allergic reactions can occur with any dose of a drug, but sensitization is more likely to be achieved with continuous drug dosing rather than single-dose therapy.[182] Rarely, an allergic reaction may be dose-dependent, as with penicillin-associated hemolytic anemia, which is observed only with continuous intravenous dosing of ≥20 million units daily. More commonly, once a patient has been sensitized to a drug, the severity of the reaction is usually proportional to the dose administered. The frequency of exposure to a given allergic compound has consistently been shown to increase the risk of an immune response, particularly involving IgE. Humoral drug sensitivity is finite, and there is a large degree of interpatient variation in the duration of sensitivity. As such, the shorter the interval between treatment regimens with a sensitizing drug, the more likely the patient will have retained sensitivity and be able to mount an allergic reaction.[2,140,182,189]

Proposed patient-specific risk factors include age, sex, genetic predisposition, and concomitant conditions. Allergic reactions to some drugs have been reported more commonly among patients in specific age groups; however, age has not been consistently identified as a risk factor.[3,191] For example, anaphylaxis associated with penicillin has been reported more commonly in patients between the ages of 20 and 49 years than in children.[192] This finding relates less to the specific age of the patient than to the number of potential exposures to the specific allergenic drug. Within the age of 20–49 years, a greater likelihood exists that a patient has been previously exposed and possibly sensitized to a penicillin, thereby increasing the risk of reactivity on subsequent exposure. Allergic drug reactions do occur in children, particularly in those who receive frequent courses of antibiotics for chronic otitis media, chronic bouts of bronchitis, or infections associated with cystic fibrosis. Therefore, the frequency and number of exposures, rather than age, are more likely to increase risk. For unknown reasons, drug allergy occurs more frequently in female than male patients. Bigby et al.[191] reported a 35% higher incidence of drug-induced allergic cutaneous reactions in women than in men.

Genetic factors may influence a patient's risk of drug allergy. In order for T-helper cells to recognize a drug as an antigen, the drug immunogen must be copresented with MHC class molecules.[169,170,173] In this regard, patients with certain MHC characteristics (or human leukocyte antigens [HLA]) may be at higher risk of reacting to a given antigenic compound as compared with patients without the specific MHC molecules. For example, in patients infected with human immunodeficiency virus (HIV), susceptibility to abacavir-induced hypersensitivity has been found to be associated with the of HLA-B*5701, HLA DR7, and HLA-DQ3.[193,194] HLA-DR4 was present in 19 of 26 patients (73%) with hydralazine-associated lupus-like syndrome, as compared with 4 of 16 hydralazine-treated patients without lupus (25%).[195] Most recently, a single nucleotide polymorphism of HLA-DRA, a MHC Class II gene, was found to be a predictor of skin-test positivity to amoxicillin and other penicillins, but not cephalosporins.[196] A number of HLA alleles have been found to be associated with allergic-mediated severe cutaneous drug reactions (see section Cutaneous Diseases).

In addition to encoding for histocompatibility phenotypes, genetic factors can influence the metabolic deactivation of drugs via phase 1 or phase 2 metabolism. For example, severe reactions to sulfamethoxazole have been noted in patients with hereditary deficiency in *N*-acetyltransferase (slow acetylators).[197] Rieder et al.[198] reported that 19 of 21 patients (90%) with sulfonamide hypersensitivity were slow acetylators, as compared with a 55% frequency of slow acetylators in a race-matched control group ($p < 0.008$). It has also been suggested that patients with a hereditary deficiency in epoxide hydrolase are at higher risk of anticonvulsant hypersensitivity syndrome because of a lesser ability to detoxify the arene oxide metabolite of the aromatic anticonvulsants.[199,200] In addition to encoding for drug metabolic activity, genes also encode for the type of T-cell receptor and costimulatory molecules/cytokines involved in the signaling of allergic reactions.

Although often implicated as a predisposing factor, atopy has not been found to increase the risk of drug allergy.[184,190] Patients who are atopic have high IgE responsiveness to environmental allergens, manifesting as allergic rhinitis, allergic asthma, and atopic dermatitis. Originally, it was theorized that the high IgE responsiveness reported in atopic patients could increase the risk of IgE sensitization to drugs. Studies have shown that a history of atopy does not influence the likelihood of a patient being sensitized to a drug. However, if an atopic patient becomes sensitized to a drug, evidence suggests that the reaction will be more severe than that observed in nonatopic patients.[2,189]

Concomitant viral infections may also predispose a patient to an allergic drug reaction. Pullen et al.[201] reported ampicillin-associated morbilliform rash in 18 of 19 patients (95%) with acute Epstein–Barr virus (EBV) infection. In comparison, a morbilliform skin rash develops in approximately 5% to 10% of the general population exposed to an aminopenicillin (e.g., ampicillin, amoxicillin).[202] Patients infected with other viral pathogens, such as human herpesvirus 6 (HHV-6) and HIV, have also exhibited an increased risk of drug allergy. In HIV-infected patients, 29–65% of those treated with sulfamethoxazole exhibited an allergic or allergic-like reaction, and the risk of reactivity to a number of other drugs (e.g., ciprofloxacin, dapsone, foscarnet, penicillins, phenytoin, rifampin) has also been shown to be increased.[203] HHV-6 has been linked to an increased risk of DRESS.[204,205] The mechanism by which viral infections increase the risk of drug reactivity is not completely understood. Proposed mechanisms include virally mediated alterations in drug metabolism, upregulation of MHC class II molecules on APCs, and increased release of cytokines such as interferon β, which amplify the immune response.[168,173,174]

Cystic fibrosis is a risk factor for allergic reactions to β-lactam antibiotics. At least 20% of patients with cystic fibrosis have an allergic reaction during an antibiotic treatment course, and the risk increases with the number of treatment courses.[206] The most commonly reported allergenic β-lactam antibiotic in these patients was piperacillin in a 1994 study[207]; however, increased rates of reactivity have also been demonstrated with other antipseudomonal penicillins and cephalosporins.[208,209] Evidence suggests that these reactions are not typically mediated by the β-lactam ring, but are more likely to be reactions to the side chains of the agents.[206]

Risk factors for nonimmune DHRs are highly dependent on the specific causative drug. For example, the risk of an anaphylactoid reaction associated with a radiocontrast agent is higher in women, patients with atopy or asthma, and patients receiving nonselective or selective β-adrenergic blocker therapy.[210-212] Risk factors for ACE inhibitor-induced angioedema include black race, a history of idiopathic angioedema secondary to a deficiency in complement-1-esterase inhibitor, and receiving longer-acting agents (i.e., enalapril, lisinopril).[141,213,214] Aspirin intolerance manifesting as aspirin-induced asthma is more commonly observed in patients with history of asthma with or without allergic rhinitis or nasal polys.[10,11,215] Aspirin- or NSAID-induced exacerbations of urticaria or angioedema are more common in atopic patients with history of idiopathic urticaria or angioedema.[216]

The most reliable risk factor for hypersensitivity and most nonimmune DHRs is history of a prior reaction to the drug. For example, patients with a history of an anaphylactoid reaction to a radiocontrast agent have a 16–44% risk of having a reaction on re-exposure particularly to a high-osmolarity agent.[217] For the penicillins, a reliable skin testing method with a high negative predictive value has allowed for more accurate determinations of the risk of reactivity on re-exposure. In a patient with a positive history of an IgE-mediated reaction to a penicillin, a positive skin-prick test revealed a 50–70% risk of an IgE-mediated reaction on re-exposure.[2,218] In contrast, a negative skin test indicates only a 2–3% risk of an IgE-mediated reaction on re-exposure.[218] Unfortunately, reliable skin-test reagents for other highly allergenic drugs have not been produced, thereby limiting the ability to accurately assess the risk of reactivity to other allergenic drugs.

MORBIDITY AND MORTALITY

In 2002, a task force assembled by the Immunotoxicology Technical Committee, part of the nonprofit Health and Environmental Sciences Institute, provided an estimate of the impact of drug-induced allergic reactions on the healthcare system.[219] On the basis of the assumption that 6–10% of adverse drug reactions are immune-mediated, it was estimated that 137,000–230,000 hospital admissions in 1998 in the United States were attributed to drug-induced allergic reactions. Using cost estimates determined in 1997 for the treatment of adverse drug reactions in hospitalized patients, the task force estimated that the annual cost of hospital-based management of drug allergy is $275 million to $600 million.[219] It was further hypothesized that the total annual cost for management of both inpatient- and outpatient-related drug allergic reactions could approach $1 billion.

PREVENTION

ALLERGIC REACTIONS

Drug-induced allergic reactions have consistently been considered as unpredictable in nature and largely unpreventable. However, continuing advances in pharmacogenomics research may alter the level of preventability of these events. Prospective screening for the presence of the HLA-B*5701 allele has been shown to lower the risk of hypersensitivity to abacavir.[193] In a double-blind, controlled study, 1,956 HIV-infected patients were randomly assigned to undergo either prospective screening for HLA-B*5701 prior to the initiation of abacavir or a standard-of-care approach to abacavir therapy.[193] Prospective screening for HLA-B*5701 with subsequent avoidance of abacavir in identified carriers prevented the occurrence of immunologically confirmed hypersensitivity reactions. Screening was associated with a negative predictive value of 100% and a positive predictive value of 47.9% in this primarily white population.[193] The investigators calculated that only 14 patients would have to be screened to prevent one case of abacavir hypersensitivity. Screening for the HLA-B*5701 allele is currently available. Screening for other HLA alleles is also available for patients considered as high risk for serious cutaneous adverse reactions to allopurinol, carbamazepine, phenytoin, and fosphenytoin (see section Cutaneous Reactions).

Once a patient has had an allergic reaction to a drug, a number of measures can be taken to prevent a subsequent reaction. The most important preventive measure is patient education. In particular, patients should be educated regarding avoidance of the causative drug and any cross-reactive drugs in the future. If a potentially immunogenic medication is deemed necessary, the use of graded challenge and induction of drug tolerance (i.e., desensitization) can often be used to prevent reactions on drug re-exposure.[220,221] A graded challenge procedure, or test dosing, involves the cautious administration of a drug when the risk of a reaction is considered to be low. Graded challenge does not alter the immune or nonimmune response to the drug.[221] Instead, it is used when the risk of an immediate reaction to a drug or related drug on re-exposure is deemed low, no alternative agent is equally effective, and a reliable skin testing method is not available. Classic examples include the slow introduction of furosemide in a patient with history of sulfonamide allergy or the slow introduction of a third-generation cephalosporin in a patient who previously developed a reaction to a first-generation cephalosporin. The starting dose is typically 1/10th–1/100th of the final treatment dose, and doses are increased in two- to fivefold increments every 30 or 60 minutes until the full therapeutic dose is attained.[221,222]

In contrast, temporary induction of drug tolerance, also known as desensitization, is used to modify a patient’s response to a drug. Such procedures are intended to alter the immune response and render mast cells less responsive to degranulation. The term *desensitization* should be used when the underlying mechanism of the drug intolerance is believed to be IgE-mediated (e.g., anaphylaxis due to penicillin).[220] The incremental dosing used in a desensitization protocol allows for downregulation of the immune response and temporary administration of the inciting agent. Reactions most amenable to desensitization are IgE-mediated involving the skin (e.g., angioedema, urticaria), upper and lower respiratory tract (e.g., dyspnea and wheezing), and cardiovascular (e.g., hypotension). Neither graded challenge nor desensitization should be used in patients with history of severe non-IgE-mediated drug allergies manifesting as DRESS, SJS, TEN, exfoliative dermatitis, hemolytic anemia, or hepatitis.

Guidelines for the avoidance of allergic reactions to common drug allergens are provided below.

Table 6-8 Skin Testing for IgE Responsiveness to β-Lactam Antibiotics

Step 1. Epicutaneous (scratch, prick) test with benzylpenicilloyl–polylysine (Pre-Pen) and the minor determinants. Make a nonbleeding scratch of the skin with a lancet. Administer the dose of the reagents (below):

- Pre-Pen, full-strength dilution; 1 drop
- Penicillin G, 10,000 units/mL; 1 drop

Step 2. Evaluate the scratch sites within 10–15 minutes. A positive test result is the presence of itching or an erythematous or wheal reaction at either site of the scratch tests. If the reaction is positive, do not proceed with further testing.

Step 3. If the scratch test is negative, proceed with intradermal testing.

- Pre-Pen, full strength; 0.02 mL intradermally
- Penicillin G, 10,000 units/mL; 0.02 mL intradermally
- Administer a positive control (histamine) and a negative control (saline)

Step 4. Evaluate the sites of intradermal injections within 15–20 minutes. A positive reaction is the presence of itching, erythema or wheal >4 mm, or a wheal reaction >50% the size of the original size of the bleb from the injection of either Pre-Pen or the minor determinants (penicillin G). Assess the site of histamine and saline control. If the histamine control site is not positive, consider interference by antihistaminergic agents.

β-LACTAM ANTIBIOTICS

Whenever possible, a non-β-lactam antibiotic should be used in patients with a history of penicillin allergy. If a β-lactam antibiotic is therapeutically necessary (i.e., treatment of syphilis in a pregnant woman, patient with cystic fibrosis and pneumonia) in a patient with history of IgE-mediated allergy, epicutaneous (prick, scratch) skin testing is the preferred technique for assessing the likelihood of a reaction on re-exposure. The skin-testing procedure is described in Table 6-8. Penicillin is rapidly hydrolyzed to a number of reactive metabolites or antigenic determinants. Ninety-five percent of the penicillin molecules that covalently bind to proteins are in the form of benzyl penicilloyl, commonly regarded as the major determinant of penicillin. The parent drug and reactive metabolites found in lesser quantities, such as penilloate and penicilloate, are referred to as minor determinants. Both the major and minor determinants can elicit an IgE-mediated response; thus, both are recommended for use when skin testing for IgE responsiveness. Penicilloyl polylysine (PPL), the major determinant bound to protein, is commercially available as Pre-Pen. The minor determinants are not commercially available in the United States; however, kits containing both the major and minor determinants are available in Europe (Diater Labs, Madrid Spain).[223] In the United States, a dilute concentration of penicillin G (10,000 units/mL) is recommended with PPL for skin testing.[224] Studies have shown a similar reaction rate to oral penicillin in patients with skin-test negativity to PPL plus penicillin G versus those with skin-test negativity to the full set of major and minor determinants.[224,225] When used together for skin testing (i.e., PPL and diluted penicillin G), 97% of patients with a negative skin test have subsequently tolerated a penicillin.[226] Patients with a positive skin test to either determinant and a positive allergy history have a 50–70% risk of reacting with an IgE-mediated response to penicillin on re-exposure.[226] This risk of β-lactam mediated reactivity can also be applied to semisynthetic penicillins and, with lesser certainty, to cephalosporins and carbapenems.[227,228] Little to no risk of a cross-reaction exists between penicillin and aztreonam, a monobactam.[229] A negative penicillin skin test indicates that the risk of an immediate type I reaction to penicillin or another β-lactam is extremely low. These patients are candidates for treatment with full therapeutic doses of a penicillin or a related β-lactam. Of note, skin testing with PPL and the minor determinant(s) does not identify patients who are at risk for unique side-chain mediated reactions to β-lactams (e.g., third-generation cephalosporins, piperacillin).

It is important to keep in mind that skin testing only indicates the potential for an IgE-mediated reaction to penicillin. Skin testing does not quantify the risk of having an IgG-, an IgM- or a cell-mediated reaction. Patients with a history of SJS, exfoliative dermatitis, or TEN associated with a penicillin should not undergo skin testing.

In addition to β-lactam-mediated allergic reactions, side-chain-specific reactions are increasingly reported with a number of penicillins, particularly the aminopenicillins and piperacillin.[230,231] As such, a patient with an allergy to one of these penicillins may not react to other penicillins. Structural similarities and differences between the penicillins are depicted in **Figure 6-1**. In a patient with history of an urticarial or other IgE-mediated reaction to an aminopenicillin or piperacillin, skin testing with Pre-Pen and the minor determinants is the preferred method to rule out β-lactam-mediated allergy. If the skin test result is negative, the patient may be challenged with a penicillin with a structurally different side chain. Dilute concentrations of amoxicillin and piperacillin have also been used to skin test for side-chain-mediated reactions.[232,233] In addition to causing side-chain-mediated allergic reactions, some penicillins have been associated with the development of nonimmunologically mediated drug eruptions. Maculopapular rash with an aminopenicillin (i.e., amoxicillin, ampicillin) may be an idiosyncratic reaction, particularly in a patient with acute EBV infection.[201,230]

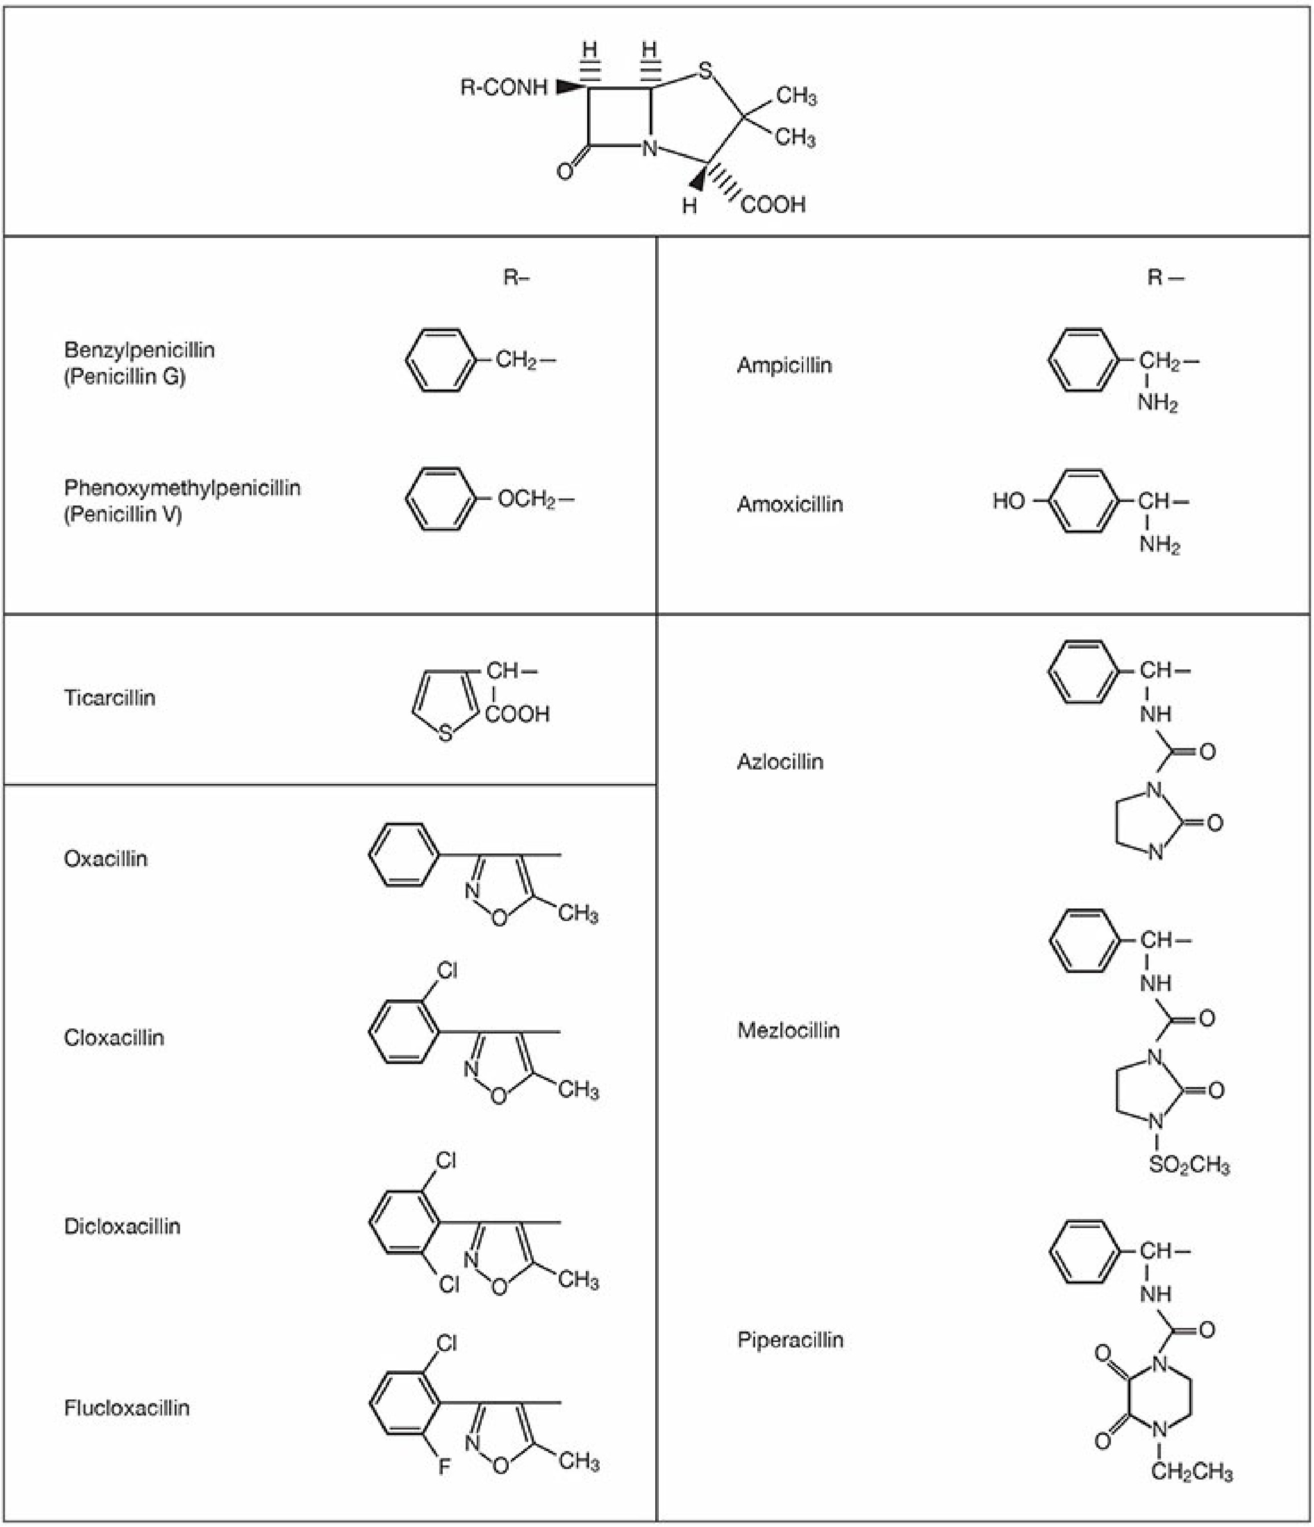

FIGURE 6-1 Similarities and Differences in the Structures of Various Penicillins

The risk of cross-reactivity between penicillins and cephalosporins is low, particularly between penicillin and the second- and third-generation agents. On the basis of laboratory studies, the risk of cross-reactivity between penicillins and the first-generation cephalosporins is less than 10%, and the risk of a cross-reaction between the penicillins and the third-generation cephalosporins is as low as 1%.[2,52] One meta-analysis included nine studies in which the risk of cephalosporin allergy was compared in penicillin-allergic and nonpenicillin-allergic patients. Compared to nonallergic patients, the risk of cross-reactivity in penicillin-allergic patients was highest in association with the first-generation cephalosporins (OR 4.79, 95% CI 3.71–6.17).[234] The first-generation agents included in the analysis (i.e., cephalothin, cephaloridine, cephalexin) had R1 substitutions similar to that of penicillin. The odds ratios for risk of cross-reactivity to the second- and third-generation cephalosporins were not significant at 1.13 (95% CI 0.61–2.12) and 0.45 (95% CI 0.18–1.13), respectively.[234] The lower risk of cross-reactivity between these agents and penicillin may be attributed to structural differences in the R1 substitution on the β-lactam ring. In patients with a history of maculopapular rash associated with a penicillin, the benefits of using a second- or third-generation cephalosporin may substantially outweigh the potential risk of a cross-reaction. In patients with a history of an IgE-mediated reaction and skin-test positivity to penicillin, first-generation cephalosporins should generally be avoided. If deemed medically necessary, a cephalosporin can be administered via a graded challenge, or attempts can be made to desensitize the patient to the cephalosporin.[22]

CARBAPENEMS

Carbapenems contain a β-lactam ring attached to a modified thiazolidine ring with two side chains. The risk of a cross-reaction between a penicillin and a carbapenem appears to be much lower than originally described. In three retrospective studies of patients with a history of penicillin allergy, the rates of cross-reaction to a carbapenem (e.g., imipenem, meropenem) were 9.2%, 9.5%, and 11%.[235-237] Each study was limited by its retrospective design, heavy reliance on self-reported penicillin allergy histories, and the lack of skin testing to confirm IgE reactivity. In prospective studies, both skin testing and carbapenem challenge dosing were used to assess cross-reactive risk.[238-242] In one of these studies, patients with negative results on skin testing for imipenem underwent graded challenge dosing of imipenem to a total dose of 500 mg.[239] None of the 110 patients reacted to imipenem. A low risk of cross-reactivity between meropenem and penicillin was demonstrated in two studies, one involving children ages 3–14 years.[240,241] In both studies, only one patient with skin-test positivity to penicillin had a positive skin test to meropenem. Graded challenge dosing with meropenem was tolerated in 100% of the skin-test-negative patients in both studies.[240,241] Most recently, cross-reactivity between penicillin and ertapenem, meropenem and imipenem was studied in 212 patients with skin-test positivity to a penicillin.[242] None of the 212 patients had skin test positivity to a carbapenem, and 211 successfully completed graded challenge dosing to a full therapeutic dose of each carbapenem.[242] Based on these results, carbapenem use should not be routinely avoided in a patient with history of penicillin allergy. Depending on the allergy history, challenge dosing with the carbapenem may be appropriate. In cases of skin test positivity to penicillin or history of severe penicillin allergy, desensitization may be performed.[243] The risk of cross-reactivity between the carbapenems is also unknown. Imipenem-sensitive patients tolerating meropenem following graded challenge and meropenem desensitization have been reported.[243,244]

CEPHALOSPORINS

A patient with a cephalosporin allergy should be interviewed in depth to obtain information on all antibiotics that have evoked allergic reactions and those that have been administered without adverse incident. Patients with a history of reactivity to one cephalosporin may or may not exhibit reactivity to other cephalosporins or penicillins.[23] Although cephalosporins share the antigenic β-lactam ring of the penicillins, they are more likely to cause allergic reactions mediated by side chains at either the R1 or R2 positions. Structural similarities and differences in the cephalosporins based on R1 and R2 substitutions are depicted in **Figure 6-2**.

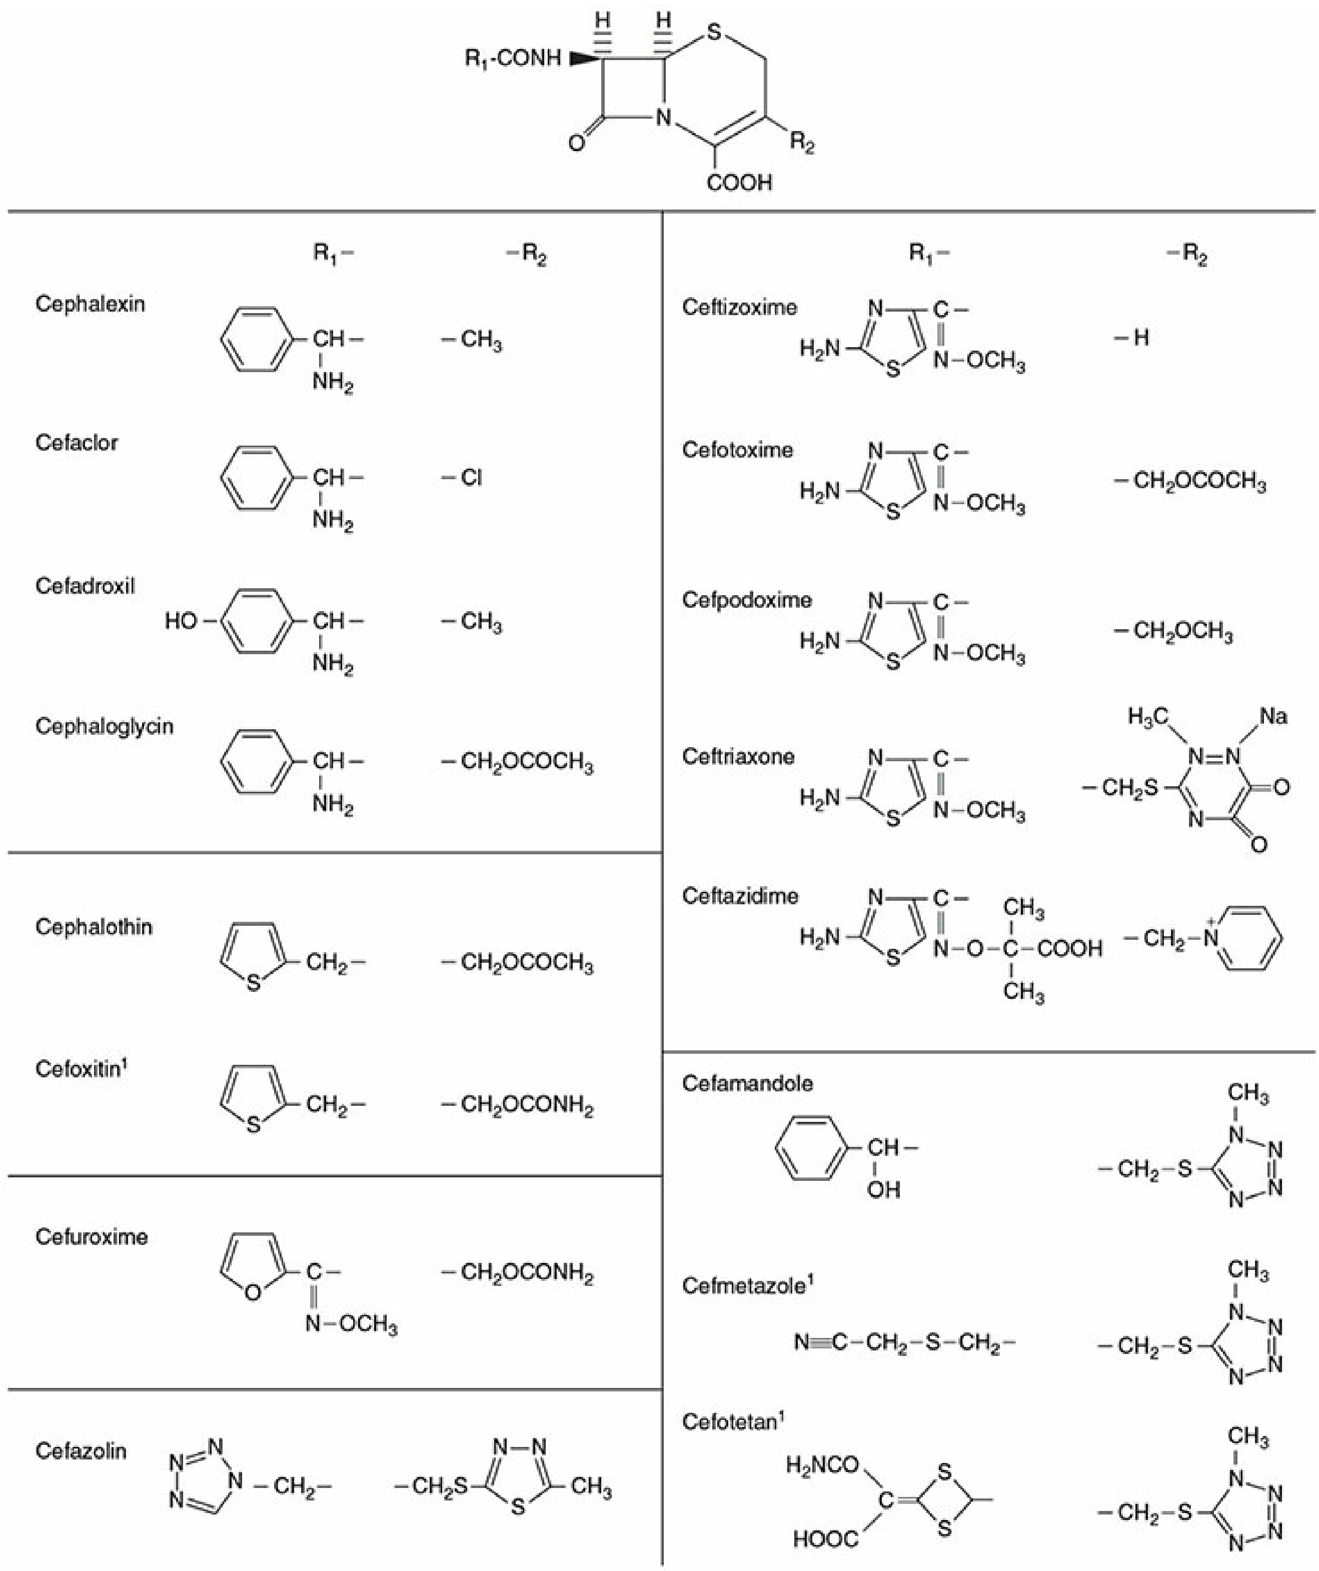

FIGURE 6-2 Similarities and Differences in the Structures of Various Cephalosporins

Source: Reprinted with permission from Baldo BA. Penicillins and cephalosporins as allergens—structural aspects of recognition and cross-reactions. *Clin Exp Allergy*. 1999; 29:744–9.

In a patient with a history of an urticarial or other IgE-mediated reaction to a cephalosporin, either the antigenic β-lactam ring or an antigenic side chain of the cephalosporin may serve as the antigenic determinant. Skin testing with Pre-Pen and the minor determinant can help to identify the likelihood of a β-lactam allergy. More commonly, allergic reactions to cephalosporins are mediated via the R1 side chain. Examination of the cephalosporin's side chains may aid in the determination of potential cross-reactive agents. For example, cefaclor and cephalexin have identical side chains at the R1 position and cephalothin and cefotaxime have similar side chains at the R2 position.[21] Ceftazidime shares a common side chain with aztreonam.[2,22] Overall, the risk of cross-reactivity between cephalosporin antibiotics is believed to be greater than the risk of cross-reactivity between the cephalosporins and the penicillins.[22] In patients with selective allergy to a cephalosporin, decisions regarding the use of alternative cephalosporins should be based on the severity of the allergic reaction, the availability of equally effective non-β-lactam antibiotics, and the structure-specific feature (i.e., R1 and R2 substitutions) of the cephalosporin.

SULFA DRUGS

In a patient with a documented or reported sulfa allergy, the first step in prevention of a subsequent reaction is accurate and complete history taking. Clarification is needed regarding the specific sulfa drug to which the patient reacted in the past, and whether he or she has taken other sulfa drugs without incident. Sulfa drugs, by definition, possess a sulfamoyl (SO_2NH_2) moiety. Sulfate salts (e.g., morphine sulfate, atropine sulfate), sulfites, and sulfides are not members of the "sulfa" drug class. Sulfa drugs include sulfonamide antibiotics, thiazide diuretics, loop diuretics (e.g., bumetanide, furosemide, torsemide), oral sulfonylurea hypoglycemic agents, carbonic anhydrase inhibitors (e.g., acetazolamide, dorzolamide), celecoxib, metolazone, sumatriptan, and zonisamide.[245] The antiviral agents amprenavir, fosamprenavir, and darunavir are also classified as sulfa drugs. This drug class can be further categorized based on the presence or absence of an aromatic amine group in the N4 position. Sulfonamide antibiotics (e.g., sulfadiazine, sulfamethoxazole, sulfapyridine, amprenavir) have an arylamine at the N4 position, whereas the sulfonamide nonantibiotics (as listed above) do not.[171,245] Presence of an arylamine at the N4 position may influence the type of reactivity to a sulfa drug and the potential for the sulfa drug to be reactive.[171,246] Compared with nonantibiotic sulfonamides, the sulfonamide antibiotics are associated with a higher frequency of severe allergic reactions such as SJS. Sulfonamide antibiotics also have an N1 substituent consisting of a 5- to 6-member heterocyclic ring containing >1 nitrogen, which has been linked to the development of IgE-mediated reactions.[171,246] Structural differences between the sulfonamide antibiotics and the nonantibiotic sulfonamides are illustrated in **Figure 6-3**.

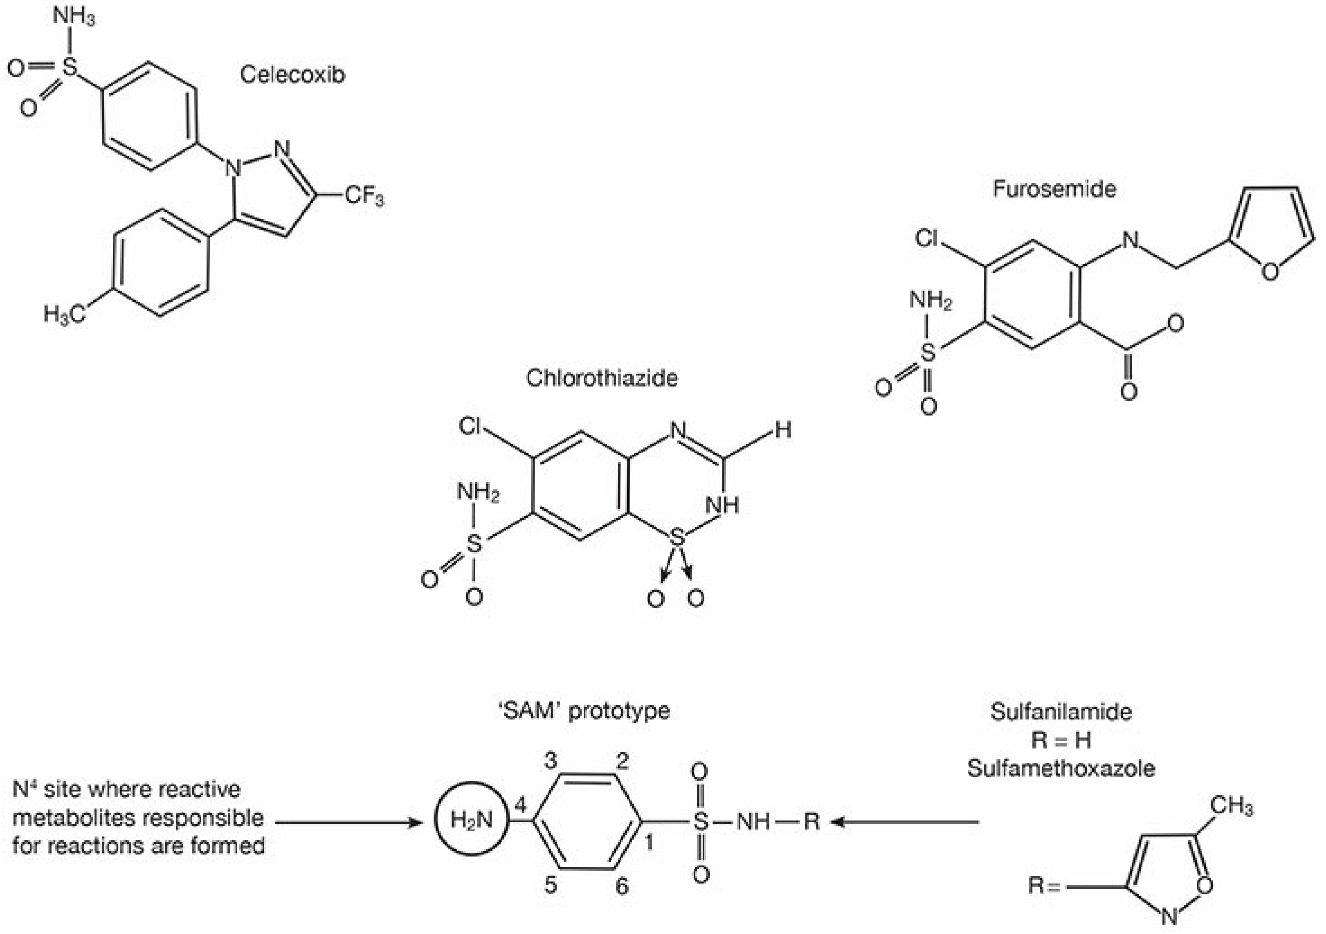

FIGURE 6-3 Structural Differences Between the Sulfonamide Antibiotics and the Nonantibiotic Sulfonamides

Source: Reprinted with permission from Shapiro LE, Knowles SR, Weber E et al. Safety of celecoxib in individuals allergic to sulfonamide: a pilot study. *Drug Saf.* 2003; 26:187-95.

Although sulfa drugs are well recognized as allergenic, the risk of reactivity to a specific sulfa drug and the risk of cross-reactivity to other sulfa drugs are not completely known. The lack of a commercially available, reliable reagent for skin testing limits the value of such testing for determination of sulfa allergy. Arndt and Jick, as part of the Boston Collaborative Drug Surveillance program, compared the frequency with which different sulfa drugs caused allergic reactions in a cohort of prospectively monitored inpatients.[247] The risk of reactivity to sulfamethoxazole was the highest at 6% (10 of 169), followed by sulfisoxazole (1.7%, or 8 of 462), chlorothiazide (0.28%, or 2 of 707), hydrochlorothiazide (0%, or 0 of 1,263), and tolbutamide (0%, or 0 of 702).[247] On the basis of this study, sulfamethoxazole is frequently cited as the most reactive of the sulfa class. Strom et al.[248] studied the risk of cross-reactivity between a sulfonamide antibiotic (e.g., sulfamethoxazole) and nonantibiotic sulfonamides (e.g., acetazolamide, loop diuretic, sulfonylurea, thiazide) in a retrospective cohort. Study patients received a nonantibiotic sulfonamide at least 60 days after having experienced an allergic reaction to a sulfonamide antibiotic. The risk of an allergic reaction in these patients within 30 days of receipt of the nonantibiotic sulfonamide was compared with that of a control group of patients without history of sulfa allergy. Of the 969 patients with history of sulfa allergy, 96 (9.9%) had a reaction to the nonantibiotic sulfonamide as compared with 315 (1.6%) of the 19,257 patients without a history of sulfa allergy.[248] Based on the results of this study, the risk of a cross-reaction between the sulfa subclasses is considered low. In fact, patients in this study with a history of sulfonamide antibiotic allergy exhibited a higher risk of subsequent reactivity to a penicillin (14%) than to a nonantibiotic sulfonamide (9.9%). When interpreting the findings of this study, consideration should be given to study design (i.e., retrospective cohort) and the broad definition for drug allergy that included eczematous reactions.

In a patient who is allergic to a specific sulfa drug (e.g., sulfamethoxazole) and requires treatment with another sulfa agent (e.g., a loop diuretic), the severity of the patient's previous allergic reaction is an important factor. Sulfa drugs can cause serious mucocutaneous events such as SJS and TEN, and they can also cause relatively mild maculopapular rash or other isolated skin rash. The severity of the reaction should largely influence the decision as to whether the causative sulfa drug or other sulfa drugs should be administered in the future. Although the structures of the sulfa agents may influence reactivity, cases of suspected cross-reactions between sulfonamide antibiotics and nonantibiotics have been reported.[249,250] If therapy with a sulfa drug is deemed necessary in a patient with history of sulfa allergy, administration of graded challenge doses should be considered. At least two cases have been published describing the successful administration of graded challenge doses of loop diuretics in patients with a history of sulfa allergy.[251,252] Desensitization to hydrochlorothiazide has also been described, starting with 0.025 mg followed by 10-fold incremental dosing every 15 minutes to a final dose of 25 mg.[253]

TETRACYCLINES

The risk of cross-reactivity between the tetracyclines is unknown. Serum sickness-like reactions have been reported in association with tetracycline, doxycycline, and minocycline.[254] Minocycline is considered to be the most antigenic agent in the tetracycline class, based on the number and severity of reported cases (i.e., lupus-like syndrome, serum sickness-like reaction).[82] The antigenicity of minocycline has been attributed to its unique amino acid side chain.[254] Until more is known about the antigenic properties of this drug class, it may be best to avoid the use of all tetracyclines in patients with a history of a severe reaction to any specific tetracycline.

AROMATIC ANTICONVULSANTS

A high degree of cross-reactivity exists between the aromatic anticonvulsants (e.g., carbamazepine, phenobarbital, phenytoin).[255] In vitro lymphocyte testing has revealed cross-reactivity between all three of these anticonvulsants in 40 of 50 patients (80%) with anticonvulsant hypersensitivity syndrome (AHS).[199] Thus, patients with AHS associated with one aromatic anticonvulsant should be advised to avoid the others. Moreover, family members of patients with AHS may be at increased risk of this syndrome.[256] In patients in whom AHS develops, underlying seizure disorders can be safely treated with benzodiazepines, gabapentin, or valproic acid. Oxcarbazepine, the 10-keto derivative of carbamazepine, has exhibited both in vitro and in vivo cross-reactivity with carbamazepine. Some patients with carbamazepine-induced AHS have been subsequently treated with oxcarbazepine without incident, while others have had severe cross-reactions.[257,258] Lamotrigine, a structurally dissimilar anticonvulsant, has also been reported to cause an anticonvulsant hypersensitivity syndrome due to an unknown mechanism.[109] For information on prevention of DRESS and SJS due to anticonvulsants, see section Cutaneous Diseases in this chapter.

BIOLOGICS

The increasing overall prevalence of anaphylaxis is attributed, in part, to the increased use of biologics. This drug class consists of monoclonal antibodies, fusion proteins, and recombinant proteins derived from living sources such as yeast, bacteria, animal cells, or mammalian cells.[259] Examples of biologics include recombinant insulin, erythropoietin, interferon β, human growth hormone, cetuximab, infliximab, omalizumab, adalimumab, ustekinumab, secukinumab, and rituximab. These large proteins can serve as complete antigens. The immunogenicity of these agents is largely related to production methods (e.g., presence of contaminants or stabilizing agents, degree of protein glycosylation, presence of nonhuman protein sequences), and administration (e.g., route of administration, rate of infusion, frequency of use).[259] Some immune reactions to these agents result from the development of neutralizing antibodies that can blunt the biologic agent's ability to exert its intended effect. Neutralizing antibodies occur in up to 60% of patients treated with infliximab, and they have also been shown to develop against natalizumab, interferon β-1b, and interferon β-1a.[259]

Preventive strategies to limit immune-mediated reactions to biologics are highly variable and dependent on the culprit agent. With infliximab, the concomitant administration of prednisone or low-dose methotrexate has been shown to suppress the formation of anti-infliximab neutralizing antibodies.[259,260] Omalizumab, a humanized monoclonal antibody targeted against IgE, is associated with the development of delayed onset anaphylaxis.[261,262] Patients treated with omalizumab are advised to carry an epinephrine auto-injector during and 24 hours after drug administration, and they should be observed for 2 hours after the first three omalizumab injections and for 30 minutes after subsequent injections.[261,262] Cetuximab, a human-murine IgG1 monoclonal antibody, causes anaphylaxis via an oligosaccharide on the Fab portion of the agent's heavy chain.[263] This same oligosaccharide, galactose-α-1,3,-galactose is present in the Lone Star tick and the serum of nonprimate mammals (i.e., certain ingested meats).[25] Up to 20% of cetuximab-treated patients in specific regions of the southern United States developed severe reactions to cetuximab on first exposure, potentially explained by cross-reactions involving pre-existing IgE antibodies against galactose-α-1,3,-galactose.[264] In addition to allergic reactions, biologics may also cause nonimmune DHRs. Depending on the agent, the preventive strategy may include decreasing the rate of drug infusion, pretreatment with antihistamines or corticosteroids, or concomitant administration of corticosteroids. Desensitization protocols have also been described for infliximab, cetuximab,and rituximab.[265,266]

DRUG HYPERSENSITIVITY REACTIONS

Unlike allergic reactions, the administration of pretreatment regimens can prevent many DHRs. Recommended pretreatment regimens for selected agents are provided in **Table 6-9**. In addition, some DHRs are best prevented by avoidance of the causative agent and other pharmacologically similar drugs in the future.

ACE INHIBITORS

Patients with ACE-inhibitor-induced angioedema should be educated to avoid all ACE inhibitors in the future. Re-exposure to the causative agent or to another ACE inhibitor may result in more severe reactions.[267] In addition to women and African Americans, an additional risk factor for ACE-inhibitor-mediated angioedema is concomitant use of the neprilysin inhibitor sacubitril. Inhibition of neprilysin leads to accumulation of bradykinin. To avoid the risk of additive inhibitory effects on bradykinin metabolism, it is recommended that patients undergo a 36-hour washout when switching from ACE inhibitor therapy to combination therapy with sacubitril–valsartan.

Although angiotensin-receptor blockers (ARBs) have no direct effects on the catabolism of bradykinin, angioedema associated with the use of an ARB has been described.[268] In a meta-analysis of 35,000 patients treated with an ARB, the weighted incidence of angioedema was 0.11%.[269] ARBs may cause angioedema by a mechanism independent from that of ACE inhibitors; thus, the term *cross-reactivity* may not directly apply to these events. ARBs are not contraindicated in patients with a history of ACE-inhibitor-induced angioedema, but they should be used with caution after careful weighing of the perceived benefits and risks of therapy. Gavras and Gavras[270] described 10 patients with a history of ACE-inhibitor-induced angioedema who were subsequently treated with an ARB without incident. In a more comprehensive systematic review of 71 patients with ACE-inhibitor angioedema, the risk of subsequent angioedema associated with an ARB was 9.4% for possible cases and 3.4% for confirmed cases.[146] None of the events was fatal. As a preventive strategy in this setting, consideration should be given to the severity of the event (i.e., diffuse versus localized angioedema) and to prior responsiveness to treatment before switching a patient from therapy with an ACE inhibitor to an ARB.

Table 6-9 Approaches to Help Prevent Drug Hypersensitivity Reactions

Hypersensitivity reactions (in general)

- With high-risk drugs, monitor for signs and symptoms of allergy during the first 7–30 days of therapy
- Be vigilant in monitoring patients who are frequently exposed to allergenic drugs (e.g., patients with cystic fibrosis, patients with frequent bouts of bronchitis, pneumonia, or otitis media)
- Educate patients about high-risk drugs and the signs of an allergic reaction
- Obtain detailed histories of allergies, with attention to the causative agent(s) and the severity of the reaction(s)
- Educate patients with a documented allergy to avoid the causative drug in the future (depending on the severity of the reaction)
- Educate patients to avoid drugs structurally similar to the causative agent (depending on the severity of the reaction)
- Educate patients to read drug labels, particularly if the patient is reactive to excipients

Immediate reactions to radiocontrast media (high- or low-osmolarity agent)

- Pretreat using prednisone 50 mg orally, administered at 13 hours, 7 hours, and 1 hour before administration of the contrast agent; diphenhydramine 50 mg orally/IV/IM 1 hour before the procedure, and ephedrine 25 mg orally 1 hour before the procedure (avoid ephedrine in patients with unstable angina, hypertension, arrhythmias)[278]
- In an emergency situation, the following pretreatment regimen has been used: hydrocortisone 200 mg IV immediately upon determination of need for the radiocontrast study and every 4 hours until the procedure is completed; diphenhydramine 50 mg IV/IM 1 hour before the procedure[278]

Immediate reaction to paclitaxel

A number of different pretreatment regimens have been used with success:

- Pretreat with dexamethasone 20 mg orally at 12 hours, 6 hours, and 1 hour before paclitaxel infusion; diphenhydramine 50 mg IV 30–60 minutes before the infusion; cimetidine 300 mg IV (or ranitidine 50 mg IV, famotidine 20 mg IV) before the paclitaxel infusion[280]
- Diphenhydramine 50 mg IV, famotidine 20 mg IV and dexamethasone 20 mg IV, each given 30 minutes before the paclitaxel infusion[281]

Vancomycin red man syndrome

- Administer each 1-g vancomycin dose over at least 1 hour; each 1.5-g dose over at least 90 minutes; each 2-g dose over 2 hours
- Pretreat using diphenhydramine 25–50 mg IV, acetaminophen 650 mg orally, hydrocortisone 100 mg IV

IM = intramuscular, IV = intravenous.

SALICYLATES

Patients with a history of an allergic or allergic-like reaction to a salicylate present a clinical challenge to the caregiver. Aspirin and NSAIDs can cause both true allergic reactions (e.g., ibuprofen-induced anaphylaxis)and nonimmune DHRs (e.g., exacerbations of asthma, urticaria, angioedema).[271] In this setting, it is crucial to obtain an accurate allergy history. If a patient's history suggests reactivity to a specific NSAID and lack of reactivity to NSAIDs of other chemically dissimilar classes, a true allergic reaction should be suspected.[10] Such patients should be advised to avoid the specific NSAID and any structurally similar agent (e.g., all propionic acid derivatives) because of the risk of cross-reactivity. In patients with asthma who describe an exacerbation after the administration of aspirin or another COX-1 inhibitor, a nonimmune DHR should be suspected.[10] These patients are at risk of severe asthma exacerbations resulting from the pharmacologic effects of aspirin and other potent COX-1 inhibitors on prostaglandin and leukotriene synthesis.[183] Inhibition of COX-1 results in a shifting in the metabolism of arachidonic acids into leukotrienes that cause bronchoconstriction and increased mucus production. Overexpression of leukotrienes may also explain the development of aspirin-induced angioedema and urticaria. Patients with aspirin- or NSAID-induced asthma, urticaria, or angioedema should be advised to avoid all COX-1 inhibitors.[10,183] Studies of short duration involving small numbers of patients with aspirin-induced asthma have shown that the COX-2 inhibitors celecoxib and rofecoxib do not exacerbate asthma.[272-274] In addition, acetaminophen at single doses <1 g, sodium salicylate, choline salicylamide, and magnesium trisalicylate have not been shown to exacerbate asthma because of their lack of effect on the COX-1 enzyme. In patients with aspirin-induced nonimmune DHRs who require aspirin for prevention of cardiovascular disease, both graded challenge and desensitization is recommended.[275] A two-dose challenge of 40.5 mg (one half of an 81-mg tablet) given 90 minutes apart has shown promising results in patients with a history of isolated dermatologic reactions to aspirin.[275] If no reaction occurs after the second dose, cardioprotective therapy with 81 mg of aspirin may commence. In patients with aspirin-induced asthma, desensitization to aspirin has been achieved.[275] Rapid desensitization protocols for patients with cardiovascular disease requiring aspirin have also been described.[275-277]

RADIOCONTRAST MEDIA

Nonimmune DHRs associated with radiocontrast agents may be prevented by the use of pretreatment regimens, as noted in Table 6-9. In addition, administration of a low-osmolarity agent in conjunction with pretreatment has been shown to reduce the risk of reactivity to approximately 1%.[278] Most recently, there is a trend toward skin testing of patients with prior history of reactivity to a radiocontrast agent. Skin testing with a panel of different agents may aid in the identification of an agent of low reactive risk, thereby reducing the risk of reactivity on subsequent exposure.[279]

MANAGEMENT

Recommended treatment regimens for drug allergy vary based on the signs and symptoms of the reaction and the type of allergic syndrome. Reactions mediated by nonimmune mechanisms are treated in a manner similar to those of true allergic reactions, with the choice of therapy based on the patient's signs and symptoms. **Table 6-10** provides a summary of recommended treatments for a variety of allergic syndromes.

In 2015, the Joint Task Force of the American Academy of Allergy, Asthma, and Immunology and the American College of Allergy, Asthma, and Allergy updated the Practice Parameter on the Diagnosis and Management of Anaphylaxis.[184] On the basis of these guidelines, patients with stridor, respiratory distress, wheezing, hypotension, cardiac arrhythmias, shock, or loss of consciousness require immediate treatment. Life-threatening conditions may also develop in patients with nonlife-threatening symptoms on initial presentation (e.g., localized urticaria).[184] Table 6-10 summarizes the Joint Task Force's guidelines for treatment of anaphylaxis. The mainstays of therapy are epinephrine 1 mg/mL dilution administered intramuscularly, oxygen, and aggressive intravenous fluid replacement. In studies of adults and children not experiencing anaphylaxis, epinephrine has been shown to be most efficiently absorbed when administered intramuscularly, rather than subcutaneously.[282] In adults, the preferred intramuscular site of injection is the anterolateral thigh, because of a higher rate of absorption.[283] Consideration should also be given to the addition of a histamine H_1-receptor blocker and histamine H_2-receptor blocker; however, these agents are not rapid-acting and should never be used in place of epinephrine. Patients receiving long-term β-blocker therapy by either oral or topical routes usually require higher doses of epinephrine.[184] In these patients, anaphylaxis is often severe and associated with profound hypotension or bradycardia that are unresponsive to epinephrine. Glucagon may be used in these patients for its inotropic and chronotropic effects that occur independently of α-receptor responsiveness. Corticosteroids have no role in the acute treatment of anaphylaxis, except for patients with a history of asthma or idiopathic angioedema; however, these drugs are used adjunctively to prevent the late-phase reaction. Patients treated long term with ACE inhibitors may also require aggressive treatment for hypotension associated with anaphylaxis. In these patients, the release of angiotensin II as a normal compensatory mechanism is blunted. Following treatment and resolution of anaphylaxis, the patient should receive education on the self-administration of epinephrine auto-injectors. Patients at high risk for recurrence of anaphylaxis should be instructed to carry two auto-injectors at all times.[184] Adults should receive the 0.3- or 0.5-mg dose (if available) and children should receive the auto-injector that provides 0.15 mg per dose.[284] The optimal dose for obese patients has not been determined. Concerns in the obese population are optimal weight-based dosing and adequate needle length for intramuscular delivery of epinephrine.[284]

Table 6-10 Management of Drug Allergy

Anaphylaxis[179,180,184]

- Discontinue the offending agent
- Establish and maintain airway
- Administer epinephrine 1 mg/mL (adults 0.3–0.5 mg; children 0.01 mg/kg) IM in the lateral aspect of the thigh
- Place patient in a recumbent position
- Oxygen 4–10 L/min through facemask or up to 100% oxygen as needed
- Repeat IM epinephrine every 5–15 minutes for up to 3 injections if the patient is not responding
- Establish IV line for venous access; keep line open with 0.9% saline solution; for hypotension or failure to respond to epinephrine, administer 1–2 L at a rate of 5–10 mL/kg in the first 5–10 minutes; children should receive up to 30 mL/kg in the first hour
- Consider nebulized albuterol 2.5–5 mg in 3 mL saline every 20 minutes for 3 doses; in children, 0.15 mg/kg via nebulizer every 20 minutes for 3 doses
- In cases of refractory bronchospasm or hypotension not responding to epinephrine because a β-adrenergic blocker is complicating management, administer glucagon 1–5 mg (20–30 mcg/kg; maximum 1 mg in children) IV over 5 minutes
- Give epinephrine by continuous IV infusion for patients with inadequate response to IM epinephrine and IV saline; add 1 mg (1 mL of 1 mg/mL) of epinephrine to 1,000 mL of 0.9% saline solution; start infusion at 2 mcg/min and increase up to 10 mcg/min based on blood pressure, heart rate, and cardiac function
- Consider intraosseous access if IV access is unsuccessful in either adults or children
- Consider diphenhydramine 25–50 mg IM/slow IV infusion in adults, then 25–50 mg orally every 4–6 hours; 1 mg/kg (up to 50 mg) in children
- Consider ranitidine 50 mg (adults) or 12.5–50 mg (1 mg/kg) in children, diluted in D5W to a volume of 20 mL administered IV over 5 minutes; given every 6–8 hours
- Consider methylprednisolone 1–2 mg/kg/dose up to 125 mg (or equivalent steroid) to reduce the risk of recurring or protracted anaphylaxis; dose can be repeated every 6 hours as required

Angioedema[184,235,286]

- Discontinue the causative agent
- Establish and maintain airway
- Treatment is based on the extent and severity of the clinical presentation; treatment may include the following:
    - Histamine H_1-receptor antagonist (see Urticaria)
    - Epinephrine (see Anaphylaxis)
    - Corticosteroids (see Anaphylaxis)
    - Nebulized (β_2-agonists (see Anaphylaxis)

Urticaria[285,286]

- Discontinue the causative agent
- Administer epinephrine if the diagnosis of anaphylaxis has not been excluded
- First-line therapy (if tolerated): hydroxyzine hydrochloride 25–150 mg daily at bedtime or in divided doses, diphenhydramine 12.5–50 mg per dose every 4 to 6 hours as needed
- Alternative first-line therapy: nonsedating antihistamines such as cetirizine 10–40 mg daily or in divided doses (adults); loratidine 10–40 mg daily in morning; fexofenadine 180 mg daily or 60 mg twice daily
- Second-line therapy: doxepin 25–100 mg/day (adults); 25–50 mg/day initially up to a maximum of 100 mg/day (adolescents); 1–3 mg/kg/day (children)
- Combinations of antihistamines are also recommended
- Short course of oral corticosteroids if symptoms are severe and not resolving with antihistamines

Serum sickness-like disease[69,188]

- Short course of methylprednisolone
- Corticosteroids (1–2 mg/kg prednisone or equivalent) once daily or administered in 2 divided doses for 5 days (if severe systemic event)

Vasculitis[86-88]

- Discontinue the offending agent
- Histamine H_1-receptor antagonist (diphenhydramine or hydroxyzine) for pruritus
- Corticosteroids (1 mg/kg prednisone or equivalent) in divided doses for 7–14 days or bolus IV therapy with 15 mg/kg/day for 3 days followed by 1 mg/kg/day orally

Hypersensitivity syndrome[188]

- Discontinue the offending agent
- Systemic corticosteroids (>0.5 mg/kg/day prednisone or equivalent)

D5W = 5% dextrose in water, IM = intramuscular, IV = intravenous.

Treatment of immune complex diseases is highly variable and dependent on the patient's presentation. In many cases, discontinuation of therapy with the causative drug is the only treatment required. Supportive therapy may include a mild analgesic/antipyretic, such as acetaminophen, for flu-like symptoms. An oral antihistamine should be considered in patients with pruritus associated with an urticarial, maculopapular, or mixed skin rash. In some patients, a short course of a low-dose oral corticosteroid such as methylprednisolone may be used for treatment of a diffuse erythematous, maculopapular skin rash. High-dose corticosteroids (i.e., prednisone 40–60 mg/day) should be reserved for patients with systemic events involving the kidney or liver, patients with drug hypersensitivity syndromes, or patients with vasculitis.[188] The presence of mucosal involvement (i.e., SJS or TEN) often precludes the use of systemic corticosteroids because of the risk of infectious complications.[188]

INFORMATION FOR PATIENTS

Patients in whom an allergic reaction to a drug develops should be educated as to the name of the specific drug, the terminology used to describe the reaction, and the likelihood of having a similar or more severe reaction upon re-exposure to the drug. If the reaction was severe (e.g., anaphylaxis, SJS), the patient should be advised to wear a medical alert tag or bracelet describing the reaction. In the case of a severe immediate reaction to a drug or chemical, the patient may be prescribed injectable epinephrine in an easily injectable form (e.g., EpiPen or EpiPen Jr.) for use in an emergency situation. Such patients should be advised to have at least two doses of epinephrine in their possession, particularly if they live in a rural area without direct access to emergency care. In addition, these patients must be counseled regarding the appropriate administration technique to ensure rapid absorption (i.e., intramuscularly into the anterolateral thigh).

Patients with a history of allergy to a drug or multiple drugs should be encouraged to ask questions about newly prescribed medications. For example, a patient allergic to a sulfa drug should be advised to question whether any newly prescribed medication is considered a "sulfa medication." Patients with aspirin-induced asthma or reactions to excipients should be encouraged to read the labels of nonprescription medications to identify ingredients of concern. In addition, patients should be educated regarding the avoidance of the causative drug and other cross-reactive drugs in the future.

CUTANEOUS DISEASES

The spectrum of adverse cutaneous reactions ranges from the commonly occurring, often self-limiting erythematous rash to the rare, life-threatening severe cutaneous adverse reactions (SCARs). Approximately 30 different drug-mediated cutaneous reaction patterns have been described.[287] This section will address drug-induced acne, erythematous reactions, fixed drug eruptions, psoriasis, and the SCARs (DRESS, SJS, TEN, warfarin tissue necrosis). The previous section provides discussion of urticaria, angioedema, and skin reactions associated with immune complex diseases. Chapter 8 provides a review of drug-induced photosensitivity.

Standard terms are used to describe the manifestations of skin lesions, including those that are drug-induced. A listing of these terms and their definitions is provided in **Table 6-11**.[287]

CAUSATIVE AGENTS

Identifying the most likely cause of a potential drug-induced cutaneous reaction is complicated by the fact that almost all drugs have been associated with rash as described in the product literature. To streamline the assessment of causality, it is important to consider that antimicrobial agents have been consistently identified as the most frequent offenders in cutaneous eruptions, followed in frequency by the NSAIDs.[288,289]

Table 6-11 Glossary of Terms for Skin Lesions[287]

Bullae

- Vesicle filled with serous fluid, >1 cm

Comedone (open)

- Blackhead; dilated hair follicle filled with sebum and bacteria with a blackened mass of skin debris at the surface

Comedone (closed)

- Whitehead; dilated hair follicle filled with sebum and bacteria with an obstructed opening to the skin

Macule

- Circumscribed, nonpalpable, red, flat lesion, <1 cm

Nodule

- Papule that is firm and with depth, 0.5–2 cm

Papule

- Solid, palpable, red, elevated lesion, <1 cm

Patch

- Group or cluster of macules

Plaque

- Solid, palpable, elevated solid lesion, 0.5 cm

Pustule

- Vesicle filled with purulent material

Typical target or iris lesion

- Lesion <3 cm in diameter, regular round shape, well-defined border with at least three different zones (two concentric rings around a central area); one ring consists of palpable edema, paler than the central area

Target lesion (flat, atypical)

- Round lesions with only two zones and/or a poorly defined border and nonpalpable, with the exception of a potential central blister

Wheal

- Central blister, irregular, pink in color, superficial area of skin edema

Vesicle

- Circumscribed, elevated lesion filled with serous fluid, 0.5 cm

---

Based largely on reports of single cases, more than 100 drugs have been implicated as causative of SJS or TEN.[288] In a large international case-control study, Roujeau et al.[288] attempted to quantify the association between the use of specific medications and the development of SJS and TEN. Cases (n = 245) were patients admitted to the hospital with a diagnosis of SJS or TEN, and controls (n = 1,147) were patients admitted to the same hospital for an elective procedure or treatment of an acute condition not deemed to be drug related. Of the drugs used for short periods, sulfonamides were the most strongly associated with TEN (crude RR 172, 95% CI 75–396), with trimethoprim–sulfamethoxazole accounting for 69% of these cases.[288] Thiazide diuretics and sulfonylureas were not associated with increased risk. In descending order of frequency, other major drug offenders were chlormezanone (crude RR 62, 95% CI 21–188), cephalosporins (RR 14, 95% CI 3.2–59), quinolones (RR 10, 95% CI 2.6–38), tetracyclines (RR 8.1, 95% CI 1.5–43), and aminopenicillins (RR 6.7, 95% CI 2.5–18).[288] Additionally, acetaminophen was associated with a significant risk (RR 9.3, 95% CI 3.9–22) in all countries other than France. Of the drugs administered for a duration of months to years, carbamazepine, phenobarbital, phenytoin, valproic acid, the oxicam NSAIDs, allopurinol, and corticosteroids were associated with significantly increased risks. The first 2 months of long-term drug administration was identified as the highest-risk period.

In 2007, the results of the Euro-SCAR study offered an update on the risks of SJS/TEN with newly marketed medications.[290] In this international, multicenter case-control study, 379 patients with SCAR and 1,505 controls were enrolled. The results of this study confirmed the high risks previously identified associated with the use of anti-infective sulfonamides, allopurinol, carbamazepine, phenobarbital, phenytoin, and the oxicam NSAIDs.[290] An increased risk of SJS/TEN was also identified with the use of nevirapine (RR >22) and lamotrigine (RR >14), with weaker associations identified with sertraline (RR 11, 95% CI 2.7–46), pantoprazole (RR 18, 95% CI 3.9–85), and tramadol (RR 20, 95% CI 4.4–93).[290] The majority of SCAR cases occurred within 8 weeks of initiation of therapy. Onset of the SCAR within 4–28 days after drug initiation was most suggestive of the drug as the cause.

Medications most commonly associated with the development of skin eruptions are listed in **Table 6-12**.[188,249,250,288,290-334] In addition to prescription medications, it is important to consider that SCARs have been associated with the use of nonprescription drugs (e.g., acetaminophen, pseudoephedrine) and traditional Chinese herbal medicines.[335]

Table 6-12 Agents Implicated in Drug-Induced Cutaneous Diseases

Drug	Incidence	Level of Evidence[a]
ACNE		
Androgenic steroids (methyltestosterone, testosterone, nandrolone)291	NK	C
Azathioprine	NK	C
Corticosteroids292,293	NK	C
Cyclosporine	NK	C
Danazol	NK	C
EPIDERMAL GROWTH FACTOR RECEPTOR INHIBITORS294,295		
Cetuximab	88–90%	B
Erlotinib	75%	B

ACE = angiotensin-converting enzyme, DRESS = drug rash with eosinophilia and systemic symptoms, HHV-6 = human herpesvirus 6, NK = not known, NSAID = nonsteroidal anti-inflammatory drug.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Prevalence.

EPIDEMIOLOGY

Cutaneous and mucocutaneous events are the most commonly reported adverse reactions to medications. Based on the results of the Boston Collaborative Drug Surveillance program conducted in the 1970s and 1980s, it is estimated that a drug-related skin rash develops in 2–3% of all hospitalized patients.[191] In this prospective study of 37,000 hospitalized patients, the majority of the skin reactions were exanthematous (94%), with the remainder urticarial (5%). Approximately 2% of the reactions were fatal.[191] Epidemiologic studies conducted in the 1990s focused on estimating the incidence of SCARs. Compared to exanthematous reactions, SCARs appear to be relatively uncommon. In 1995, Roujeau et al.[188] estimated that serious cutaneous drug events including SJS and TEN occur in 1 of every 1,000 hospitalized patients.

Estimates of the prevalence of drug-induced cutaneous events have been determined from prospective studies of hospitalized patients, outpatients, patients receiving systemic drug therapy, and those exposed to medications via any route of administration.[191,289,336] The estimates have varied based on the type of cutaneous event investigated, the definition used to describe the dermatologic condition, and the population studied. In a 6-month prospective study conducted in 2000–2001, practitioners identified and subsequently a dermatologist assessed all suspected allergic cutaneous reactions that led to hospitalization or occurred during hospitalization.[289] A group of dermatologists and pharmacologists retrospectively evaluated causality. A total of 48 cases were identified, resulting in an estimated prevalence of 3.6 of 1,000 hospitalized patients.[289] The majority of the allergic reactions were exanthematous (56%), and the prevalence was significantly higher in medical (0.5%) versus surgical patients (0.01%).[289] Thirty-four percent of cases were deemed serious on the basis of leading to hospitalization (18%), increasing the duration of hospital stay (14%), or were life-threatening (2%).[289] Compared to other studies reporting an incidence of cutaneous drug reactions of 2% in hospitalized patients, the lower prevalence determined in this study can be attributed to the restricted focus on allergic-mediated skin reactions and on systemic drug exposures.[289]

TEN is estimated to occur in 0.4–1.3 cases per million person-years, while SJS occurs in 1–6 cases per million person-years.[319] The variability in these estimates of incidence can be attributed to differences in the diagnostic criteria for SJS and TEN. The prevalence or incidence of other cutaneous skin disorders is less well described. The incidence of DRESS is highly variable, occurring in 1 of 1,000 to 1 of 10,000 patients exposed to anticonvulsants and sulfonamides, and the mortality rate has been estimated to be approximately 10%.[337] The wide variability in the reported incidence of DRESS can be attributed to the variable presentation of the condition. Fixed drug eruptions occur more frequently, with reported incidences of 2.5–22%.[302] Tissue necrosis has been reported in 1 of 10,000 patients treated with warfarin and in 0.01–0.12% of patients treated with all oral anticoagulants including the coumarin products.[188,334]

MECHANISMS

Cutaneous reactions to drugs can result from both immune and nonimmune mechanisms (i.e., direct pharmacologic effects, nonimmune DHR, idiosyncrasy). Allergy is the underlying mechanism in 50% of the events, including most cases of urticaria, angioedema, serum sickness-like syndrome with maculopapular rash, fixed drug eruptions, vasculitis, and the SCARs, including DRESS, SJS, and TEN. The skin is a target for immunologically mediated reactions because it possesses APCs such as the cutaneous Langerhans cells. The presence of monooxygenases, cytochromes, and transport-associated proteins in the keratinocytes allow for transformation of low-molecular-weight drug haptens into reactive, immunogenic metabolites.[338]

T cells play a major role in the pathophysiology of drug-related cutaneous reactions. An extensive review of the role of the T lymphocyte in the mediation of a variety of drug-induced eruptions has been provided by Naisbett.[339] Based on immunohistologic studies, allergy-mediated maculopapular rashes have been shown to involve the recruitment of CD4 cells and copresentation of the drug hapten with the MHC class II molecule HLA-DR.[339] Maculopapular rashes are also associated with secretion of high levels of IL-5 and eotaxin, two cytokines involved in the recruitment and differentiation of eosinophils. Bullous reactions are more likely to be associated with the recruitment of CD8+ cells and copresentation of the haptenic drug or reactive metabolite with MHC class I molecules.[339] Cell studies of blister fluid from patients who survived TEN also support a dominant role for T lymphocytes, particularly CD8+ cells, in the pathogenesis of this SCAR. In patients with TEN, activation of cytotoxic T lymphocytes ultimately results in dermal-cell apoptosis, which is believed to be triggered via activation of the perforin–granzyme or the Fas-Fas ligand pathways. Stimulation of these pathways triggers activation of caspases, intracellular proteases that cleave a key protein within the cell, leading to keratinocyte apoptosis. In addition to cytotoxic T lymphocytes, other mediators of TEN include monocytes, macrophages, and TNFα. Overexpression of TNFα, interferon α, IL-2, and IL-5 has been reported in skin lesions of patients with SJS and TEN.[337,340]

Mechanisms by which many drugs cause skin eruptions are not known. Pharmacologic effects may be the underlying mechanism by which most drugs cause acneiform eruptions and provocation of psoriasis. Androgenic drugs (e.g., anabolic steroids, danazol, methyltestosterone) aggravate pre-existing acne or cause acneiform eruptions by activating sebaceous-gland hypertrophy and increasing sebum production. The high incidence of acneiform eruptions associated with the use of epidermal growth factor receptor (EGFR) inhibitors may also be explained in part by the known pharmacology of these agents. EGFRs are overexpressed in many solid tumors, explaining the effectiveness of EGFR inhibitors in the treatment of refractory colorectal and lung cancers. EGFRs are also expressed in the basal layer of the epidermis and in the hair follicle.[294,295] Although the mechanism by which EGFR inhibitors cause acne-like rashes is not entirely known, the dose-related incidence may be related to inhibition of EGFR signaling on epidermal epithelium leading to impaired cell growth and differentiation.[294] Provocation of psoriasis by nonselective β-blockers such as propranolol may be explained in part by blockade of epidermal β_2-receptors, resulting in a decrease in intraepidermal cyclic adenosine monophosphate and an increase in epidermal-cell turnover.[313] Cyclooxygenase inhibitors such as indomethacin may induce psoriasis by inhibiting prostaglandin synthesis, thereby shunting the metabolism of arachidonic acids to the lipoxygenase pathway. The resultant increase in leukotriene concentrations may contribute to the exacerbation of psoriasis in patients treated with COX inhibitors.[314] Studies support that leukotriene concentrations are 7–11 times higher in psoriatic lesions as compared with normal skin.[313]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The discriminating features of specific drug eruptions are provided in **Table 6-13** and the conditions to consider in the differential diagnoses are provided in **Table 6-14**.

The most common type of drug-induced skin eruption is the exanthematous or maculopapular rash, occurring in 1–5% of first-time users of implicated medications.[342] This red, inflamed cutaneous reaction usually appears as a mixture of discrete macules and papules on the trunk or dependent areas of the body (e.g., lower extremities of an ambulating patient, middle to lower back of a bedridden patient). The lesions typically spread outward in a bilateral, symmetrical pattern to involve the neck, upper and lower extremities, and potentially the face.[298,341,342] The rash is often described as "dot-like" in appearance, or measles (morbilliform)-like, and may or may not be associated with fever and pruritis. The discrete lesions typically coalesce over days into patches with large areas of confluence. The rash usually occurs within 4–14 days after the initiation of therapy with the causative drug or within 1–2 days after drug discontinuation.[341] This reaction is usually self-limited, with resolution in 1–2 weeks after drug discontinuation. Upon re-exposure to the drug, the rash may reappear within hours. In rare instances, a maculopapular rash may be the initial sign of a severe cutaneous event such as SJS. Therefore, all patients who initially present with a maculopapular rash should be assessed for hallmark signs of a more severe, progressive reaction. Lesions in the mucous membranes (e.g., conjunctiva, oral cavity, nares, genitalia) are evident in more than 90% of serious cutaneous events, and extension of the rash to the palms and soles often portends a more protracted course.[188,337]

A commonly encountered clinical challenge is differentiation of a maculopapular rash from an urticarial lesion. Unlike maculopapular lesions, urticarial lesions are typically asymmetrical, pink rather than red, and irregular in shape. These superficial wheals, largely confined to the epidermis, are often described as geographic in shape (i.e., similar in shape to the continent of Africa or Asia). Urticarial lesions are highly pruritic, vary in size from 1 mm to several centimeters in diameter, and typically develop on the chest, face, or neck within minutes to 48 hours after drug exposure.[298] Differentiation of a maculopapular rash from urticaria is important, because the latter often indicates IgE-mediated mast cell degranulation. In a patient with drug-related IgE-mediated urticaria, continuation of the causative drug may lead to a more severe reaction, including angioedema or anaphylaxis. Urticaria may also be caused by foods, insect bites/stings, and environmental factors such as sunlight, cold, and heat.[298]

Fixed drug eruptions (FDEs) are the second most commonly occurring drug-related cutaneous reaction, occurring in 0.5–22% of patients exposed to certain medications.[344] FDEs present as solitary lesions or multiple well-demarcated lesions occurring anywhere on the body, but favoring the face, lips, hands, feet, and genitalia. The lesions are round or oval in shape and range in size from 1–20 cm in diameter.[287,298] The color of the lesions may vary from dusky red, to blue-gray or violaceous. Patients typically describe a burning sensation or itching, or both, associated with the development of lesions. In some patients, the center of the lesion may become bullous and result in denuding of skin. The diagnostic hallmark of FDE is recurrence of the lesion in the same anatomical location after drug rechallenge.[302] Both topical and oral provocation tests have been performed to confirm the diagnosis. However, oral challenge is more likely to lead to the development of generalized bullous lesions.[302] Following resolution of lesions, the affected tissue may remain hyperpigmented for an extended period. As the name implies, the sole cause of FDE is drugs. Therefore, a complete drug history with attention to prescription, nonprescription, and herbal remedies must be obtained to identify the causative agent. Drugs most commonly associated with FDE are listed in Table 6-12.

Table 6-13 Signs and Symptoms Associated with Drug-Induced Cutaneous Diseases

Acne[298]

- Papules and pustules on face and upper trunk
- Limited number of comedones to no comedones

Erythematous rash[341,342]

- Symmetrical distribution of macules and papules starting on upper trunk or legs
- Rash may progress to entire body including face
- Pruritus (50%)
- Redness without blistering

DRESS[337,343]

- High fever (38–40°C)
- Diffuse, symmetrical maculopapular rash with pruritus (90%)
- Facial and periorbital edema
- Enlarged lymph nodes at ≥2 sites (cervical and inguinal) in >50% cases
- Involvement of at least one internal organ (hepatitis, pneumonitis, pancreatitis)
- Conjunctivitis
- Eosinophilia
- Atypical lymphocytosis

Fixed drug eruption[287,344]

- Initial burning “stinging” sensation or itching of skin
- Round or oval dusky red to violaceous lesions, 1–20 cm in diameter, favoring the face, lips, hands, feet, perineal area, genitalia
- Lesions recur in the same location(s) upon rechallenge
- Blistering of lesions
- Anorexia and malaise (infrequent)
- High fever (infrequent)

- Hyperpigmentation in the area of the lesion following recovery

Psoriasis

- Red or salmon-pink plaques covered by silvery scales symmetrically distributed on elbows, knees, scalp, and lumbosacral region

SJS/TEN[188,319,337]

- Prodrome of nausea, vomiting, sore throat, cough, arthralgias, myalgias for 2–8 days before rash development
- Widespread erythematous, purpuric rash with flat atypical target lesions
- Burning and painful sensation of the skin
- Fever (10–30% of cases of SJS, 100% of cases of TEN)
- Facial edema
- Mucosal lesions of the mouth, lips, nasal cavity, conjunctivae, genitalia (92–100% of cases of SJS; 85–95% of cases of TEN)
- Epidermal detachment (<10% of body surface area with SJS; >30% of body surface area with TEN)
- Positive Nikolsky sign (TEN)
- Neutropenia (30% of cases of SJS and TEN)
- Lymphopenia (90% of cases of TEN)
- Thrombocytopenia (15% of cases of TEN)
- Prerenal azotemia (TEN)
- Elevated aspartate and alanine aminotransferases (50% of cases of SJS and TEN)
- Hypopigmentation or hyperpigmentation (88% of cases of TEN)
- Keratitis and corneal erosions

Warfarin-induced skin necrosis[188,298,334]

- Poorly demarcated, painful red plaques with soft-tissue edema
- Pain
- Petechial hemorrhages that coalesce into large hemorrhagic bullae with areas of gangrenous tissue
- Lesions usually distributed in areas of fatty tissue (buttocks, breasts, hips)

DRESS = drug rash with eosinophilia and systemic symptoms, HHV-6 = human herpesvirus-6, SJS = Stevens–Johnson syndrome, TEN = toxic epidermal necrolysis.

Acneiform eruptions are an infrequent drug-induced adverse event, accounting for only 1% of all drug-related cutaneous reactions.[298] Unlike acne vulgaris, drug-related acneiform eruptions consist primarily of papules and pustules with limited to no comedones. Similar to those associated with acne vulgaris, these eruptions are typically confined to the face and upper trunk.[298] The classic drug offenders are corticosteroids, adrenocorticotropic hormone, anabolic steroids, combination oral contraceptives, danazol, bromides, iodides, isoniazid, lithium, and azathioprine. Corticosteroids administered orally, parenterally, topically, or by inhalation have been shown to provoke acneiform eruptions or exacerbate underlying conditions of acne.[291,292,293] Steroid-induced acne is common and usually appears within 14 days after initiation of systemic or topical therapy. An acne-like reaction has also been described in association with the use of the EGFR inhibitors (e.g., cetuximab, panitumumab, erlotinib, gefitinib) used in the treatment of colorectal and non-small-cell lung cancer. The acne-like rash is pruritic, with a predominance of pustules and an absence of open or closed comedones.[294,295] The rash is typically mild to moderate in severity, occurs most frequently on the face and V-shaped areas of the chest, back, or both, and appears within 10–14 days after drug therapy initiation. The severity of the rash has been shown to correlate with both increasing drug dose and the antitumor activity of the agent.[295] Some data support a relationship between the occurrence of rash and the increased likelihood of patient survival.[294] In patients with severe rashes, particularly those involving more than 50% of the body surface area, dose modification or interruption of EGFR inhibitor therapy is recommended.[294,295] The rash is typically reversible following discontinuation of therapy.

Table 6-14 Conditions to Consider in the Differential Diagnosis of Drug-Induced Cutaneous Disorders

Erythematous rash[298,342]

- Viral exanthema (Epstein–Barr virus, human herpesvirus 6, parvovirus B19)
- Acute graft-versus-host disease
- Bacterial toxin eruption
- Kawasaki disease
- Still disease

Fixed drug eruption[287,302,344]

- Bullous pemphigoid
- Contact dermatitis
- Herpes (simplex) labialis
- Discoid lupus erythematosus
- Insect bite (if a single lesion)
- Phytophotodermatitis

DRESS[188]

- Cutaneous lymphoma
- Psoriasis (aggravation of)[313,314]
- Alcohol consumption
- Physical trauma
- Psychological stress
- Streptococcal infection
- Viral infection

SJS[188,345]

- Postinfectious erythema multiforme (secondary to herpes simplex or mycoplasma infection)
- Kawasaki disease

TEN[188]

- Exfoliative dermatitis

- Staphylococcal scalded-skin syndrome
- Paraneoplastic pemphigus
- Thermal burns

Warfarin-induced skin necrosis[334]

- Disseminated intravascular coagulation
- Purple toe syndrome
- Pyoderma gangrenosum
- Microembolization
- Leukocytoclastic vasculitis
- Necrotizing fasciitis
- Purpura fulminans
- Venous gangrene
- Heparin-induced thrombocytopenia
- Septicemia

DRESS = drug rash with eosinophilia and systemic symptoms, HHV-6 = human herpesvirus-6, SJS = Stevens–Johnson syndrome, TEN = toxic epidermal necrolysis.

Psoriasis is a chronic, immunologically mediated skin disease that is characterized by red or salmon-pink plaques covered by silvery or white scales surrounded by normal skin.[313] The plaques are symmetrically distributed on the elbows, knees, scalp, and lumbosacral region. Several clinical phenotypes of psoriasis exist, including pustular, erythrodermic, and nail psoriasis. However, 90% of cases present as plaque psoriasis (psoriasis vulgaris). This chronic condition involves the activation of T lymphocytes with overexpression of a number of cytokines, including TNFα, interferon α, IL-6, IL-2, and IL-8. Drugs can exacerbate pre-existing lesions (e.g., β-blockers, lithium, synthetic antimalarial drugs), provoke the development of new plaques on the normal skin of patients with psoriasis (e.g., β-blockers, lithium), and cause psoriasis in patients with no history or familial predisposition (e.g., growth hormone).[313-315] Most cases of drug-induced psoriasis are clinically indistinguishable from psoriasis from nondrug-induced causes. In some cases, the offending drug can cause a lichenoid pattern of disease or a transformation to the pustular form of psoriasis.[313] The latency period from initiation of therapy with the offending drug to the exacerbation or appearance of psoriatic lesions varies widely. Mean latency periods of 3 weeks, 6 weeks, and 33 weeks have been described for psoriasis induced by the synthetic antimalarial drugs, ACE inhibitors, and lithium, respectively.[313] β-blockers have been associated with a latency period ranging from days to weeks after initiation of therapy. Drugs used to treat psoriasis, including topically applied agents (e.g., coal tar) and systemically administered agents (e.g., etretinate, etanercept, infliximab), can also aggravate the condition. The TNFα-agents infliximab and etanercept have been reported to aggravate psoriasis in patients undergoing treatment for psoriatic arthritis and have provoked psoriasis in patients treated for Crohn disease, ankylosing spondylitis, rheumatoid arthritis, and ulcerative colitis.[315] In patients treated with infliximab or etanercept, new psoriatic lesions developed as soon as after the second injection.[315]

Serious cutaneous adverse reactions include DRESS, SJS, TEN, and warfarin tissue necrosis. DRESS is a distinct clinical syndrome previously described by the more general term, *drug hypersensitivity syndrome*.[99,102,343] DRESS is characterized by the triad of high fever, rash, and internal organ involvement.[188,343] Compared with immune complex diseases such as SSLD, DRESS is associated with a more delayed onset of symptoms, ranging from 3 to 8 weeks after drug initiation, and a more consistent pattern of internal-organ involvement.[99,343] The initial manifestation of DRESS is diffuse, symmetrical maculopapular eruptions on the upper trunk and face. This rash can extend to include the lower extremities and is typically associated with facial and periorbital edema. The edema may lead to gross distortion of the patient's features. Organs affected by this syndrome include the kidney, liver, pancreas, lungs, and hematologic system. A high degree of interpatient variability exists with regard to the targeted organ and the severity of organ involvement. To better define and classify the syndrome, the RegiSCAR scoring system was developed in 2007.[346] Application of this scoring system in 172 cases of suspected DRESS led to the identification of the following features of a probable or definite case: skin rash, hypereosinophilia, lymphadenopathy, and liver involvement.[346]

Both the anticonvulsant hypersensitivity syndrome and the allopurinol hypersensitivity syndrome are classic examples of DRESS. Anticonvulsant hypersensitivity syndrome, associated with the aromatic anticonvulsants (e.g., phenytoin, phenobarbital, carbamazepine), is characterized by the triad of fever (38–40°C), rash (papular, pruritic, often associated with facial or periorbital edema), and lymphadenopathy occurring within 3 months after the initiation of therapy.[255,256] Other diagnostic criteria include hematologic abnormalities (leukocytosis, eosinophilia), myalgias, pharyngitis, and hepatitis or other multisystem involvement (e.g., interstitial nephritis, rhabdomyolysis, pneumonitis).[255,256] Allopurinol hypersensitivity syndrome is associated with a mean (±SD) onset of 47±109 days[102] and also presents with high fever, eosinophilia, and skin rash that may be severe (e.g., SJS or TEN). Kidney failure, hepatomegaly, and abnormalities in liver function tests are also frequently noted. This reaction, attributed to the active metabolite oxypurinol, has been described as a vasculitic immune complex disease.[101,102]

SJS and TEN are related mucocutaneous disorders that are considered by many as drug-induced variants of erythema multiforme. Like erythema multiforme, both SJS and TEN are associated with the widespread development of multiple types of skin lesions, including macules, blisters, purpuric lesions, and the hallmark target iris lesions. The target lesion is discrete, round, <3 cm in diameter, and identified by its central zone of epidermal necrosis surrounded by two concentric rings of edema and erythema.[345] SJS and TEN are progressive bullous disorders that are considered dermatologic emergencies.[288] Unlike erythema multiforme, which is usually self-limiting and related to recurrent herpes simplex viral infections, both SJS and TEN are usually drug-related and extend from diffuse erythematous reactions to include mucous membrane erosion and epidermal detachment. Drugs are the cause of SJS and TEN in 50% and 80% of cases, respectively.[287,347]

Both SJS and TEN typically occur within the first 4 weeks of drug therapy. Before skin lesions become evident, both SJS and TEN are associated with a prodromal syndrome of nausea, vomiting, sore throat, diarrhea, myalgias, and arthralgias. In patients with TEN, high fevers and a burning sensation of the skin are also frequently reported prior to the eruption of skin lesions. Mucous membrane involvement, typically of the mouth and lips, nasal cavity, and conjunctivae, tends to precede the development of skin lesions by 1–3 days.[287,348] The initial lesions are erythematous and appear on the face and upper trunk, after which they rapidly evolve into blisters and target lesions on the face, trunk, and limbs.[348] Full-thickness epidermal detachment occurs within days after the onset of skin lesions. Rather than considered as two distinctly different syndromes, SJS and TEN are often described as a continuous spectrum of a disease, with TEN as the more severe form.[345] The extent of epidermal detachment has been used to distinguish between SJS and TEN. SJS is described by the presence of mucosal erosions with widespread purpuric macules and epidermal detachment of <10% of body surface area, whereas TEN involves widespread purpuric macules and epidermal detachment of >30% of body surface area.[345,349] The term *SJS-TEN overlap* is used to describe cases in which evidence of epidermal detachment is present on 10% to 30% of the body surface area.[345,349] Although regrowth of the epidermis begins within days after the onset of epidermal loss, TEN is sometimes complicated by the development of acute kidney injury, respiratory failure, neutropenia, electrolyte abnormalities, and sepsis. Long-term sequelae of SJS and TEN may include temporary nail loss, permanent visual impairment, cutaneous scarring, and irregular pigmentation. A severity-of-illness scoring system for TEN, known as SCORTEN (SCORe of toxic epidermal necrolysis), has been described and evaluated as a prognostic indicator.[350] With the use of this system, seven independent risk factors, determined within 24 hours of patient presentation with TEN, are used as patient outcome indicators.[350]

Warfarin-induced skin necrosis (WISN) is a severe cutaneous reaction that typically begins within 10 days after initiation of warfarin therapy, with a peak occurrence between days 3 and 6.[298] WISN initially presents with red, poorly demarcated painful plaques usually in areas of high adipose tissue (e.g., breasts, hips, buttocks). The plaques can progress to hemorrhagic blisters and eventually become necrotic, requiring surgical debridement.[188,298] WISN occurs as a result of an imbalance between the concentrations of the endogenous vitamin K-dependent anticoagulant protein C and the vitamin K-dependent clotting factors.[188,298] The half-life of protein C is much shorter (8 hours) compared with those of clotting factors II, IX, and X (24–48 hours). After warfarin initiation, a rapid decline in the concentration of protein C may lead to a hypercoagulable state, resulting in WISN. This theory is supported by the fact that WISN is more likely to occur in patients who receive excessive initial doses of warfarin and have an underlying protein C deficiency. Patients with a deficiency of protein S, the cofactor for protein C activity, may also be at greater risk of WISN. WISN can be fatal if not treated.

RISK FACTORS

Female sex, concomitant viral infection with HIV or EBV, and the presence of autoimmune disease have routinely been identified as risk factors for cutaneous drug eruptions.[191,201,203] In a prospective study of 48 patients with allergic-mediated skin reactions, identified risk factors were HIV (19% of patients), connective-tissue disease (10%), and viral or autoimmune hepatitis (12%).[289] In another prospective cohort study of hospitalized patients with adverse cutaneous drug reactions, those with systemic lupus erythematosus had a relative risk of 4.68 (95% CI 1.79–12.18) and patients with acquired immunodeficiency syndrome had a relative risk of 8.68 (95% CI 2.18–33.19).[351] Studies have also been performed to identify predictors of skin rash associated with specific drugs or drug classes. In the antiepileptic drug class, an increased risk of drug rash was identified in women of reproductive age and in those with history of a rash induced by another antiepileptic medication.[352,353] Other risk factors associated with specific drugs, drug eruptions, or both are provided in **Table 6-15**.

The initial dose, rate of dose titration, and concomitant administration of interacting drugs can be risk factors for cutaneous drug eruptions. Both lamotrigine and nevirapine were identified as strongly associated with SJS/TEN in the EuroSCAR study.[290] In addition to female sex, lack of adherence to the 14-day lead-in period of dosing of nevirapine may increase the risk of SCARs.[290] Factors shown to increase the risk of rash with lamotrigine include age <13 years, history of rash caused by another anticonvulsant agent, exceeding the recommended initial dose or recommended rate of dose escalation, and coadministration with valproic acid.[354] In the EuroSCAR study, daily allopurinol doses >200 mg were associated with a higher risk of SJS/TEN (OR 36, 95% CI 17–76) compared with lower daily doses (OR 3.0, 95% CI 1.1–8.4).[290] In other analyses, both kidney disease and the lack of dose adjustment in patients with impaired kidney function have been identified as risk factors for allopurinol-induced DRESS, SJS, or TEN.[92] Excessive starting doses of warfarin, female sex, and obesity have all been identified as risk factors for WISN.[188,298]

Table 6-15 Risk Factors for Drug-Induced Cutaneous Diseases

Abacavir

- HHV-6[204,205]
- HLA-B*5701[193]

Allopurinol

- Doses >200 mg per day[322]
- Kidney disease[102,103]
- HLA-B*5801[335]

Amoxicillin and ampicillin

- EBV[201]

Aromatic anticonvulsants (carbamazepine, phenobarbital, phenytoin)

- Previous rash in response to an antiepileptic[353]
- Women of reproductive age[352]
- HLA-B*1502 (carbamazepine, phenytoin, fosphenytoin)[355,356]
- HLA-A*3101 (carbamazepine)[357]
- CYP2C9*3 (phenytoin)[358]

Lamotrigine

- Age <13 years[290]
- Exceeding the recommended initial dose[290]
- Coadministration with valproic acid[290]

Nevirapine

- Female sex[290]
- Lack of adherence to recommendation for 14-day lead-in dosing[290]
- HLA-B*3505[359]

Penicillins

- HIV[203]

Sulfonamides

- HIV[203]

Warfarin

- Female sex[334]
- Hereditary protein C or S deficiency[334]
- Large initial doses[334]

- Obesity[334]

EBV = Epstein–Barr virus, HIV = human immunodeficiency virus, HLA = human leukocyte antigen, HHV-6 = human herpesvirus 6.

Genetic susceptibility has always been suspected as a risk factor for allergic-mediated cutaneous disorders, and evidence has become available to support this hypothesis. The HLA-B*1502 allele has been strongly linked to the risk of SJS/TEN associated with carbamazepine. In a study of Han Chinese patients, all of whom developed SJS/TEN during carbamazepine therapy, had the HLA-B*1502 allele, whereas only 3% of the patients who tolerated carbamazepine had the allele.[355] This allele occurs almost exclusively in patients of Asian and South Asian Indian ancestry. In this same patient population, presence of HLA-B*1502 has been shown to increase the risk of SJS and TEN associated with carbamazepine, phenytoin, and fosphenytoin.[356] In European and North Asian populations, HLA-A*3101 has been related to the development of nonblistering reactions such as DRESS induced by carbamazepine.[357] Most recently, a genetic variant in the CYP2C isozyme, CYP2C9*3, was found in association with phenytoin-induced SCARs.[358] Presence of the HLA-B*5701 allele has been shown to increase the risk of abacavir hypersensitivity,[194] and studies in Han Chinese suggest that the HLA-B*5801 allele may be a genetic marker for allopurinol-induced SJS and TEN.[335] Preliminary evidence also suggests a higher frequency of FDEs in association with the HLA-B22 and HLA-C1 antigens.[302]

MORBIDITY AND MORTALITY

Using four national databases, Stern[336] quantified hospitalizations and visits to office-based physicians and hospital clinics for a primary diagnosis of a skin condition. The U.S. Census estimates for 2000 were used to calculate the rates of hospitalization or office visits for a diagnosis of SJS/TEN, drug eruption, drug allergy, and urticaria/angioedema. Overall, 0.06% of hospital admissions were attributed to a skin condition related to drug use.[336] Approximately 5,000 hospitalizations per year resulted from a diagnosis of erythema multiforme, SJS, or TEN, 35% of which were attributed to drug use.[336] The rates of hospitalization for a primary diagnosis of SJS/TEN and drug eruptions were calculated as 16 and 21 admissions per million person-years, respectively. During the 6 years of study (1995–2000), there were 650,000 office visits with a primary diagnosis of erythema multiforme, SJS, or TEN and 1 million visits with a primary diagnosis of drug eruption.[336] Urticaria, angioedema, and anaphylaxis were the most frequent diagnoses associated with outpatient visits, accounting for 3 times as many visits as SJS/TEN, drug rash, and drug allergy combined.[336] When the data were annualized, more than 500,000 office visits per year were attributed to drug eruptions and drug allergies including a dermatologic component.

Although rare in occurrence relative to other dermatologic conditions, SJS and TEN are associated with substantial morbidity, with the potential for lasting disabilities and complications (e.g., corneal ulcers, corneal neovascularization, skin grafts, coagulopathies, hepatitis, glomerulonephritis) in 30–45% of patients.[319] Moreover, estimates of mortality associated with SJS and TEN range from 1% to 5% and 10% to 70%, respectively.[319] In at least one study, the death rate associated with SJS and TEN was found to positively correlate with age and was 10 times higher in patients >65 years of age.[336] In cases of SJS and TEN, the most common causes of death are sepsis, pulmonary embolism, gastrointestinal bleeding, and hypovolemia.

PREVENTION

Advances in genetic testing allow for prospective screening for the HLA-B*1502 and the HLA-B*5701 alleles, biomarkers of an increased risk of severe hypersensitivity reactions to carbamazepine and abacavir, respectively. Screening for the presence of these and other biomarkers may ultimately lead to the prevention of allergy-mediated severe cutaneous reactions. Genetic tests for HLA-B*1502 and HLA-B*5701 are currently available.

Other preventive measures include the avoidance of drugs with a propensity to cause cutaneous diseases in high-risk populations (**Table 6-16**), adherence to recommended dosing guidelines specifically for dosing titration, and avoidance of drug–drug interactions. Patients who have experienced a SCAR associated with a specific drug should be counseled to avoid the use of that drug and any structurally related drug for the rest of their lives. When initiating therapy with a medication known to present a high risk of a severe cutaneous reaction, counseling should be provided regarding the initial warning signs and symptoms (i.e., burning sensation of skin, mucous membrane involvement).

Table 6-16 Approaches to Help Prevent Drug-Induced Cutaneous Diseases

Drug	Condition	Prevention
Abacavir	DRESS	Test for HLA-B*5701[194]
Allopurinol	DRESS/SJS/TEN	Adjust dose in patients with kidney disease[102] Avoid concomitant therapy with thiazide diuretics[103]
Aromatic anticonvulsants (carbamazepine, phenytoin,	SJS, TEN	Avoid use in patients with history of severe rash caused by another aromatic anticonvulsant

phenobarbital)		
Carbamazepine	SJS, TEN	Test for HLA-B*1502[355]
Lamotrigine	SJS/TEN	Adhere to recommended dose and dose-escalation recommendations[354] Avoid concomitant therapy with valproic acid[354]
Nevirapine	SJS/TEN	Adhere to 14-day lead-in dosing recommendation
Warfarin	WISN	Avoid loading or large initial doses In patients with protein C or S deficiency or previous history of WISN, overlap therapy with heparin for at least 5 days and initiate warfarin at low doses[334]

DRESS = drug rash with eosinophilia and systemic symptoms, SJS = Stevens–Johnson syndrome, TEN = toxic epidermal necrolysis, WISN = warfarin-induced skin necrosis.

MANAGEMENT

Table 6-17 provides recommended treatment methods for the drug eruptions presented in this section. Of note, maculopapular rashes are generally self-limited and usually do not require treatment. If associated with pruritus, oral antihistamines are advised. Topical corticosteroid creams such as 1% hydrocortisone may be used in patients with nondiffuse limited areas of involvement. In patients with a diffuse maculopapular rash and evidence of systemic symptoms (e.g., arthralgias, muscle pain or weakness), an oral, self-tapering, low-dose steroid regimen (e.g., methylprednisolone) may be appropriate. The recommended treatment of drug-induced urticaria and angioedema is provided in Table 6-10.

Drug-induced psoriasis is usually resistant to treatment and requires discontinuation of the offending agent (e.g., β-blockers, lithium, synthetic antimalarial drug). However, in one case series, 50% of the patients in whom psoriasis associated with either infliximab or etanercept developed were able to continue therapy and their lesions responded favorably to treatment with topical corticosteroids.[315]

Treatment of SJS and TEN is focused on supportive therapy (nutritional support, pain management, fluid replacement) and the prevention of complications such as acute kidney injury and sepsis. Depending on the extent of blistering and epidermal detachment, patients may require treatment in an intensive care or burn unit. Recommended treatment methods for SJS and TEN are provided in Table 6-17. In particular, the topical administration of silver sulfadiazine should be avoided because of the high risk of SJS and TEN associated with sulfonamides and the potential for cross-reactivity with sulfadiazine.[287] The use of systemic corticosteroids remains controversial.[345] To date, there are no large randomized, controlled studies to support the concept that systemic corticosteroids either reduce the time to recovery or prevent the development of complications. In a systematic review, a significant impact on mortality (OR 0.4, 95% CI 0.2–0.9) was demonstrated with corticosteroid use in only 1 of 6 retrospective cohort studies.[361] IVIG has emerged as a potential treatment of SJS and TEN in children and adults.[362-366] IVIG is postulated to inhibit dermal-cell apoptosis triggered via the Fas-Fas ligand pathway.[348] When administered early in the course of the disease, IVIG has shown promising effects on wound healing, progression of disease, and mortality.[362-365] Both low dose (0.2–0.5 g/kg) and high dose (2–3 g/kg) IVIG regimens have been described. Most studies support the use of a mean total dose of not less than 2 g/kg.[366] Cyclosporine (3–5 mg/kg/day for 7 days) was shown to offer a greater mortality benefit compared to IVIG (1 g/kg for 3 days) in a single-center retrospective study of 64 patients.[367] Similar to corticosteroids, the optimal doses of IVIG and cyclosporine, times of initiation, and durations of therapy are yet to be determined.

Table 6-17 Management of Drug-Induced Cutaneous Diseases

Disease	Recommended Treatment
Acne[291-298]	May or may not require discontinuation of the offending agent Topical benzoyl peroxide or retinoids
Erythematous reaction[341,342]	Discontinue offending agent Histamine H_1-antagonist (diphenhydramine 25–50 mg orally every 6 hours as needed for itching) Methylprednisolone (6-day self-tapering oral regimen starting with 24 mg on day 1) (if diffuse rash)
FDE[344]	Discontinue offending agent Sunscreen for 6 months to 1 year if areas of hyperpigmentation
DRESS[188,343,360]	Discontinue the offending agent Topical corticosteroids may be of some benefit but most cases are resistant to standard therapies
Psoriasis[270]	Discontinue offending agent Topical corticosteroids may be of some benefit but most cases are resistant to standard therapies
SJS and TEN[188,345,347,349]	IV fluid replacement (saline or lactated Ringer's solution) Nutritional support (enteral or parenteral routes) Pain control (systemic opiate therapy) Eye care—antibiotic eye drops, lubricants Oral hygiene: hydrogen peroxide gargle; anesthetics (viscous lidocaine or benzocaine); antiseptic mouthwash Topical antiseptics (0.5% silver nitrate or 0.05% chlorhexidine) Wound care with biologic dressings (porcine xenografts), synthetic dressings, or silicone dressings Surgical debridement of blisters and necrotic tissue Consider IVIG (1–2 g/kg) or cyclosporine (3–5 mg/kg/day for 7 days)

WISN188,334	Discontinue warfarin Vitamin K or fresh-frozen plasma to restore protein C or S Initiate heparin to prevent further thrombosis Protein C concentrate if patient has known protein C deficiency Skin grafting and/or surgical debridement

FDE = fixed drug eruption, DRESS = drug rash with eosinophilia and systemic symptoms, IV = intravenous, IVIG = intravenous immunoglobulin, SJS = Stevens–Johnson syndrome, TEN = toxic epidermal necrolysis, WISN = warfarin-induced skin necrosis.

INFORMATION FOR PATIENTS

Patients in whom a drug-induced adverse cutaneous event develops should be educated as to the name of the specific offending drug, the terminology used to describe the rash, and the likelihood of the occurrence of a similar or more severe reaction following re-exposure to the drug. If the reaction was allergic-mediated, the patient should be instructed to question all newly prescribed medications regarding similarity to the offending agent in chemical structure or chemical class. If the cutaneous event was severe, the patient should be advised to wear a medical alert bracelet. Patients with underlying skin conditions such as acne or psoriasis should be instructed to question whether any newly prescribed medication may aggravate the condition.

CHAPTER 7

Systemic Lupus Erythematosus-Like Syndrome

Karen W. Lee and Matthew F. Ambury

Idiopathic systemic lupus erythematosus (SLE) is an autoimmune disease of unclear etiology and pathogenesis. Clinical and laboratory findings characterizing SLE involve various organs of the body including the musculoskeletal system, skin, kidneys, and the central nervous system.[1-4] Certain drugs have been reported to cause signs and symptoms that closely mimic the presentation of SLE, and this drug-induced syndrome is often referred to as drug-induced lupus, drug-related lupus, drug-induced lupus-like syndrome, drug-induced lupus erythematosus, lupus erythematosus medicamentosus, and drug/medication-induced SLE.[1,5] For the purpose of this chapter, this syndrome will be referred to as *drug-induced lupus*.

CAUSATIVE AGENTS

Drugs that have been reported to cause drug-induced lupus are listed in **Table 7-1**.[6-202] Since sulfadiazine was first reported to cause drug-induced lupus in 1945, over 90 medications have been associated with the disease.[199,203] Although drug-induced lupus has been reported as an adverse effect in clinical trials, most of the literature is in the form of case reports.

EPIDEMIOLOGY

Approximately 5–10% of cases of SLE are drug-induced.[6,204] Using more recently published data on national prevalence of SLE, approximately 16,000–32,000 people in the Unites States are afflicted by drug-induced lupus, with some estimates as high as 50,000.[6,204,205] The estimated annual incidence of drug-induced lupus ranges from 3.2 to 9.4 cases per 100,000 persons, depending on patient-specific risk factors.[204,205] The true incidence of drug-induced lupus may in fact be much higher, as some patients may experience mild symptoms that remain unrecognized and undiagnosed.

The incidence of drug-induced lupus associated with specific agents is presented in Table 7-1.[6-202] Because the literature associating many medications with drug-induced lupus is primarily in the form of case reports, the incidence associated with specific medications is largely unknown or assumed to be less than 1%.[93] It is challenging to determine the incidence of drug-induced lupus associated with newer agents. However, drugs such as procainamide and hydralazine have been strongly associated with drug-induced lupus, and the incidence of drug-induced lupus associated with these agents is more easily estimated. Growing evidence supports a strong association between drug-induced lupus and other medications, such as chlorpromazine, isoniazid, methyldopa, quinidine, and minocycline.[83,206]

Table 7-1 Agents Implicated in Drug-Induced Lupus

Drug	Incidence	Level of Evidence[a]
MOST COMMON		
Chlorpromazine[6-20]	1%	C
Hydralazine[6,14-28]	2–21%	C
Isoniazid[6,16,18-20,29-32]	NK	C

[a]Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

MECHANISMS

Possible mechanisms of drug-induced lupus are summarized in **Table 7-2**.[50,51,83,90,207-217] Mechanisms of drug-induced lupus involve alterations in immunologic pathways or drug metabolism. Although precise mechanisms are unknown, several hypotheses have been proposed, including one or often a combination of the following mechanisms for a given lupus-inducing agent: molecular mimicry, nucleic acid alterations, immunoregulatory alterations, interference in the complement pathway, and predisposing genetic factors. Molecular mimicry involves the interaction between an implicated medication and a nucleic acid. Drugs or drug metabolites with structures that are similar to the structure of a particular nucleic acid may stimulate the production of autoantibodies to that nucleic acid, the drug, or its metabolite. This hypothesis has been supported by several studies showing structural similarities between hydralazine and the nucleic acid adenosine.[17,218]

The nucleic acid alteration hypothesis suggests that the offending drug or its metabolite may somehow alter the immune process, increasing the immunogenicity of nuclear antigens. Alternatively, the drug or metabolite may couple with an antigen to form a hapten, triggering the formation of autoantibodies. The drug or its metabolites may also damage deoxyribonucleic acid (DNA), which may also result in the formation of autoantibodies.[17,83,219] For drugs that undergo hepatic acetylation, acetylator phenotype may affect response to this damage. Fast acetylators require less DNA repair, suggesting that less damage to DNA occurs in patients with this phenotype.[17,83,219]

Defective methylation of DNA in T cells has been suggested in the pathogenesis of idiopathic SLE and may also contribute to the development of drug-induced lupus. Hypomethylation of DNA in T cells alters T-cell gene expression and function.[51] Both procainamide and hydralazine inhibit DNA methylation, which may be an important component of the development of drug-induced lupus associated with these drugs.

The immunoregulatory alteration hypothesis suggests that drug or drug metabolites may alter the function of immunoregulatory cells via direct cytotoxicity. Studies examining this hypothesis have produced inconsistent results.[220] Procainamide alters the function of T lymphocytes in vitro, enhancing or suppressing the proliferative response in a concentration-dependent fashion; high concentrations of procainamide suppress lymphocyte response, whereas low concentrations enhance this response.[213] Macrophages and mononuclear cells may also be involved in immunoregulation. It is proposed that during drug metabolism, these cells may release a variety of oxygen free radicals, which may be directly cytotoxic to lymphocytes. This cytotoxicity may lead to the loss of T suppressor cells, stimulation of B cells, and increased antibody production.[17,221] Drugs or drug metabolites may bind to the major histocompatibility antigens on monocytes, rendering them immunogenic.[17,222] The drug or the metabolite may also bind to histone antibodies, stimulating the production of antihistone antibodies.[17,217] Antitumor necrosis factor α (anti-TNF α) may promote humoral autoimmunity by selectively downregulating the induction of cytotoxic T lymphocyte response, a mechanism normally involved in controlling B-cell hyperactivity, which may induce lupus in some patients.[164,217]

Table 7-2 Mechanisms of Drug-Induced Lupus[a]

Drug	Hypothesized Mechanism(s)
MOST COMMON	
Chlorpromazine[83]	Direct cytotoxicity due to formation of reactive metabolite(s)
Hydralazine[17,83,207-210]	Interaction between hydralazine and nucleic acid adenosine leading to an increase in immunogenicity of nuclear antigens and/or formation of autoantibodies; inhibition of covalent binding reactions between C3 and C4 leading to prohibited clearing of immune complexes; slow acetylation and/or presence of certain HLA alleles; inhibition of DNA methylation; direct cytotoxicity due to formation of reactive metabolite(s)
Isoniazid[83,207,209]	Inhibition of covalent binding reactions between C3 and C4 leading to prohibited clearing of immune complexes; slow acetylation; direct cytotoxicity due to formation of reactive metabolite(s)
Methyldopa	NK
Minocycline[50,211]	Genetic predisposition due to presence of certain HLA alleles; incomplete inhibition of apoptosis pathways resulting in autoimmunity
Procainamide[51,83,209,210,212-216]	Alters function of immunoregulatory cells, including the interference of T-cell maturation, via direct cytotoxicity due to formation of the procainamide-hydroxylamine reactive metabolite; inhibition of covalent binding reactions between C3 and C4 leading to prohibited clearing of immune complexes; slow acetylation; inhibition of DNA methylation
Quinidine[83]	Direct cytotoxicity due to formation of reactive metabolite(s)
OTHERS	
Acebutolol[90]	Direct cytotoxicity due to formation of reactive metabolite(s)
Etanercept[217]	Inhibition of cytotoxic T lymphocyte induction causing down regulation in control of B-cell hyperactivity
Infliximab[217]	Inhibition of cytotoxic T lymphocyte induction causing down regulation in control of B-cell hyperactivity
Propythiouracil[83]	Direct cytotoxicity due to formation of reactive metabolite(s)
Sulfonamides[210]	Slow acetylation

DNA = deoxyribonucleic acid, HLA = human leukocyte antigen, HMG = 3-hydroxy-3-methyl-glutaryl-coenzyme, NK = not known.

[a] For drugs listed in Table 7-1 that are not listed in this table, the mechanism of drug-induced lupus is unknown.

Another immunoregulatory alteration hypothesis involves the interference of T-cell maturation in the thymus by a reactive metabolite of procainamide, procainamide-hydroxylamine. These immature T cells are then exported to the periphery and are reactive to chromatin. The T cells assist autoreactive B cells that are already in the periphery to stimulate an autoantibody response.[212,214]

It is well established that hereditary deficiencies in complements 1, 2, and 4 (C1, C2, and C4) predispose patients to idiopathic lupus and other autoimmune diseases.[17] One of the roles of the complement system is to scavenge immune complexes, promoting their clearance from the body.[223] Drug-induced lupus may occur as a result of interference in the complement pathway. Some drugs or drug metabolites may inhibit C3 activation, preventing complement from clearing immune complexes and possibly stimulating autoimmune processes. Isoniazid, hydralazine, and the hydroxylamine metabolite of procainamide have been shown to inhibit covalent binding reactions between C3 and C4.[17,209]

It has been proposed that genetic factors may play a role in the development of drug-induced lupus. The term *lupus diathesis* refers to a predisposition to idiopathic lupus. Patients with lupus diathesis are those with a personal or family history of arthritis, myalgia, drug reaction, pleuritic pain, epilepsy, or leukopenia.[207,224] In patients with lupus diathesis, certain drugs may cause the clinical expression of the disease; in contrast, medications known to cause drug-induced lupus may be used in patients with idiopathic SLE without exacerbating disease.[207,224] Other genetic factors may be important in the development of drug-induced lupus. The incidence of lupus induced by hydralazine and, to a lesser extent, procainamide is higher in slow acetylators.[210,213] This is most likely due to metabolism of hydralazine or procainamide resulting in the formation of an active metabolite. Other genetic factors have also been associated with the development of drug-induced lupus, including the presence of certain human leukocyte antigen (HLA) alleles. HLA-DR4 is found in 73% of patients with hydralazine-induced lupus, which is higher than the rate in patients with SLE (25%).[208] The HLA-DR2 and HLA-DQB1 alleles have also been found in patients with minocycline-induced lupus.[211] The presence of null alleles for the fourth component of complement (C4) has been associated with drug-included lupus.[51,225] Another hypothesis suggests that minocycline-induced lupus may occur as a result of incomplete inhibition of apoptosis pathways, leading to autoimmunity.[50]

Table 7-3 Signs and Symptoms Associated with Drug-Induced Lupus

- Anemia (serum hemoglobin <11.5 g/dL)
- Anti-dsDNA
- Antihistone antibodies

- Antinuclear antibodies
- Anti-Sm antibodies
- Anti-ssDNA
- Arthralgia
- Arthritis
- Drug-specific skin manifestations (e.g., butterfly rash, purpura, erythema nodosum, and erythematous papules)
- Elevated erythrocyte sedimentation rate
- Fever
- Hepatosplenomegaly
- Hypergammaglobulinemia
- Leukopenia (white cell count <4,000/mm^3)
- Lupus erythematosus cells
- Malaise
- Mild kidney involvement (e.g., glomerulonephritis)
- Myalgia
- Pericarditis
- Pleural effusion
- Pleuritis
- Positive Coombs test
- Pulmonary infiltrate
- Weight loss

DNA = deoxyribonucleic acid, dsDNA = double-stranded DNA, Sm = Smith nuclear antigen, ssDNA = single-stranded DNA.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms associated with drug-induced lupus are listed in **Table 7-3**. Signs and symptoms of drug-induced lupus typically present within 3 weeks to 2 years after initiation of therapy with the suspected agent.[5,19,51] Patients typically present with prodromal symptoms of arthralgia and arthritis before progression to a lupus-like syndrome, potentially affecting numerous organs.[19] Arthralgia is present in up to 90% of patients with drug-induced lupus.[206,226] Patients typically present with only one or two symptoms. Initial presentation usually involves articular symptoms characterized by polyarticular and symmetric joint involvement.[20,227] Constitutional symptoms associated with drug-induced lupus include fever, malaise, musculoskeletal symptoms (i.e., myalgia, arthralgia, arthritis), serositis (i.e., pleurisy, pericarditis, pleural effusion, pulmonary infiltrate), hepatomegaly, splenomegaly, and skin manifestations, including the signature “butterfly rash” associated with SLE.[5,17,19,20,35,227] Weight loss has also been reported in association with drug-induced lupus.[20,21,52] Autoimmune hepatitis has been reported with an incidence of 32–54% in patients with minocycline-induced lupus.[1,40,41] Pulmonary involvement with pleuropericarditis and pulmonary infiltrates is most commonly reported with lupus induced by procainamide.[16,19,52,59,60,228] Cutaneous involvement is generally less frequent in drug-induced lupus, although certain skin manifestations are actually more common as compared with idiopathic SLE, including purpura, erythema nodosum, and erythematous papules. Cutaneous manifestations occur in up to 39% of patients with quinidine- and hydralazine-induced lupus but are rarely associated with minocycline- or procainamide-induced lupus.[1,83,229] Certain drugs may induce characteristic skin manifestations unique to the medication.[5,230]

Serologic evidence in patients with drug-induced lupus typically includes a positive antinuclear antibody (ANA) test, lupus erythematosus cells, antihistone antibodies, and the absence of antibodies to DNA.[1,20,126,227,231] It is important to note that some drugs cause a positive ANA test without evidence of clinical disease.[35,231,232] Likewise, patients taking either quinidine or minocycline and exhibiting rheumatologic symptoms of lupus may not present with a positive ANA test.[16] Depending on the drug, antibody formation may be directed toward individual histones (i.e., H1, H2A, H2B, H3, H4) and/or histone complexes (i.e., H2A-2B, H3-4).[20,233,234] The antibodies present as either immunoglobulin G or immunoglobulin M.[17,19,20] Binding to single-stranded DNA has been reported in a few cases, but binding to double-stranded DNA has not been reported.[17,222] Antiphospholipid antibodies have been reported predominantly in cases of lupus induced by chlorpromazine but also in association with lupus induced by other drugs, such as hydralazine, procainamide, quinidine, valproic acid, amoxicillin, propranolol, and streptomycin.[20,235,236] Antibodies against Smith nuclear antigen (anti-Sm) are not commonly present in patients with drug-induced lupus.[2,19,20,231,237]

Elevations in the erythrocyte sedimentation rate (ESR) are very common, indicative of an inflammatory process.[1,16,17,19,51,227,231] Serum complement concentrations are generally normal; however, several reports of transient lowering of serum complement concentrations (i.e., C3 and C4) have been published.[16,17,19,20,227,231,238,239] Anemia, leukopenia, thrombocytopenia, and hypergammaglobulinemia are less common and are usually mild.[16,17,19,20,227] A positive Coombs test has been reported in cases of lupus induced by methyldopa, procainamide, and hydralazine.[19,20,52,240-244] Circulating lupus anticoagulants, due to binding of autoantibodies to phospholipids and proteins associated with the cell membrane, have been reported in patients taking chlorpromazine; however, the association of these lupus anticoagulants with the diagnosis and prognosis of drug-induced lupus is unclear.[231,245]

Drug-induced lupus is less likely than idiopathic SLE to involve the central nervous system or the kidneys.[5,17,20,123,126,231] Nonetheless, neuropathy has been reported in patients diagnosed with lupus induced by procainamide or hydralazine, and mild and reversible kidney involvement, particularly glomerulonephritis, has been noted in cases of drug-induced lupus caused by D-penicillamine, hydralazine, griseofulvin, procainamide, propylthiouracil, quinidine, and anticonvulsants.[5,14,17,19,20,126,227,231,246-253] The signs and symptoms of idiopathic SLE and drug-induced lupus are compared and contrasted in **Table 7-4**.[1,2,17,19,51,52,93,206,227,230,232,247,254-259] No specific diagnostic criteria for drug-induced lupus exist.[1,17,35] However, several investigators have identified cases of drug-induced lupus based on four patient criteria: (1) adequate exposure (dose and duration) of a drug suspected of inducing lupus, (2) temporal association of clinical manifestation upon drug ingestion with no history of idiopathic SLE prior to drug administration, (3) positive ANA test with at least one clinical symptom of SLE, and (4) remission of clinical symptoms and gradual decline in serum ANA concentrations following drug discontinuation.[5,14,16,17,19,226,231] At least one clinical symptom of SLE must be present for diagnosis because many patients can convert from ANA-negative to ANA-positive with no clinical signs or symptoms of lupus.[17] Recurrence of lupus symptoms after a rechallenge with the implicated drug strengthens the probability that the syndrome is drug-induced, although rechallenge is seldom performed.[1,39]

Table 7-4 Comparison of Signs and Symptoms Associated with Drug-Induced Lupus Versus Idiopathic SLE

Manifestations	Idiopathic SLE	All Drug-Induced Lupus	Procainamide-Induced Lupus	Hydralazine-Induced Lupus
	% of patients experiencing sign/symptom			
Alopecia	42	Unusual	0	0
Anemia (hemoglobin <11.5 g/dL)	57	0–46	9–21	30–35
Anti-dsDNA	25–80	5	Rare	Rare
Antihistone antibodies	20–60	70–95	90–95	90–95
Antinuclear antibodies	95	95	100	100
Anti-Sm antibodies	40–50	5	10–20	10–20
Anti-ssDNA	50–90	30–48	70–80	70–80
Arthralgia	92–95	75	74–95	84–95
Arthritis	86–95	75	18	50
CNS involvement	25–70	0	0–2	0
Complement concentrations	Reduced	Normal/reduced	NK	NK
Discoid lesions	23	Unusual	0	0
Erythrocyte sedimentation rate	Elevated	Elevated (80)	Elevated	Elevated
Fever	75–85	25–50	45	14–50
Hepatosplenomegaly	9–46	25	20–41	3–75
Hypergammaglobulinemia	NK	10–50	NK	NK
Kidney involvement	38–75	5	0–5	0–20
Leukopenia (white cell count <4,000/mm^3)	43–50	2–33	2–32	26
Lupus erythematosus cells	Up to 70	90	NK	NK
Malaise	75	25–50	NK	NK
Mucosal ulcers	42	Unusual	0	0
Myalgia	48	NK	20–50	2–34
Pericarditis	18–50	50	14–18	0–2
Pleural effusion	16–33	NK	33	10
Pleuritis	42–60	NK	52	14–25
Positive Coombs test	18–25	0–33	33	0–5
Pulmonary infiltrate	0–10	NK	5–20	3–25
Skin manifestations	50–75	0–10	5–18	2–39
Thrombocytopenia	NK	Unusual	NK	NK

CNS = central nervous system, DNA = deoxyribonucleic acid, dsDNA = double-stranded DNA, NK = not known, SLE = systemic lupus erythematosus, Sm = Smith nuclear antigen, ssDNA = single-stranded DNA.

To confirm a case of drug-induced lupus, one must recognize key differences between the clinical and laboratory findings characteristic of idiopathic SLE and those of drug-induced lupus. Although the presentation of SLE and drug-induced lupus appear similar on initial assessment, the underlying characteristics of each condition are not the same. The two conditions differ in terms of known risk factors, affected organs, serologic features, and severity. The diagnosis of SLE is based on the presence of four clinical or laboratory findings in a variety of organs according to guidelines compiled by the American College of Rheumatology.[2] However, no specific diagnostic criteria have been adopted for drug-induced lupus.

Idiopathic SLE presents in a younger population, ranging from 15 to 40 years of age, with an average age at presentation of 29 years. Idiopathic SLE is reported more commonly in females.[5,17,258] Unlike drug-induced lupus, idiopathic SLE often presents with antibodies to double-stranded DNA, and is less likely to be associated with antibodies to antihistones.[1] Antihistone antibodies are present in 25% of SLE cases, whereas 90% of drug-induced lupus cases present with antihistone antibodies.[5,20,227] Anemia, leukopenia, and thrombocytopenia are more common and usually more severe in patients with idiopathic SLE as compared with drug-induced lupus.[227] Other symptoms, such as butterfly rash, alopecia, discoid lesions, and mucosal ulcers are more common in idiopathic SLE.[5,231]

Because drug-induced lupus-like syndrome is characterized by a multisystem presentation, a broad spectrum of illnesses must be ruled out during a differential diagnosis. Viral or bacterial conditions must be ruled out because of the common presentation of fever and malaise. Because patients with lupus induced by certain drugs (e.g., procainamide) may present with pleuropulmonary involvement, other pulmonary diseases (e.g., pneumonia, pulmonary embolus) must be ruled out.[17] Refer to **Table 7-5** for conditions to consider in the differential diagnosis of drug-induced lupus.

Table 7-5 Conditions to Consider in the Differential Diagnosis of Drug-Induced Lupus

- Antiphospholipid antibody syndrome
- Connective-tissue diseases
- Fibromyalgia
- Idiopathic systemic lupus erythematosus
- Pleuropulmonary conditions (pneumonia, pulmonary embolus)
- Rheumatoid arthritis
- Scleroderma
- Systemic sclerosis
- Vasculitis (Wegener granulomatosis)
- Viral/bacteriologic conditions

Other chemical agents and environmental toxins may contribute to lupus-like syndrome and must be ruled out. Such factors include exposure to hydrazines (e.g., mushrooms, tobacco, tobacco smoke), aromatic amines (e.g., hair-coloring solutions), eosin (ingredient in cosmetics), tartrazine (i.e., food colorant), insecticide, and heavy metals (e.g., mercury, cadmium).[5,17,131]

Two other forms of drug-induced lupus include drug-induced subacute cutaneous lupus erythematosus (SCLE) and drug-induced chronic cutaneous lupus erythematosus (CCLE). Drugs including terbinafine, hydrochlorothiazide, acebutolol, bupropion, interferons α and β, immunosuppressive or cancer chemotherapy agents, certain angiotensin-converting enzyme inhibitors, 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins), and calcium-channel blockers have been associated with drug-induced SCLE.[89,129,154,260-263] This condition appears to be more common in females than in males, and anti-Sjögren syndrome A/B (also known as anti-Ro/La), antihistone, and ANA have been detected. Fluorouracil agents have been associated with drug-induced CCLE. Limited information regarding these types of drug-induced lupus exists.[226]

Investigation of the patient's medication profile is an important step in diagnosing potential drug-induced lupus. Because the published literature documenting drug-induced lupus is limited to case reports and does not often include medications that have recently entered the market, an understanding of the characteristics that influence the likelihood of a drug to cause lupus is critical. The biochemical structure of a drug may influence the potential for drug-induced lupus.[5,220,227] A common structural feature shared by many drugs associated with lupus is the presence of a nitrogen or sulfur heteroatom in a functional group such as the aromatic amine, hydrazine, sulfhydryl, or thiono-sulfur. Many of the drugs that have been implicated in drug-induced lupus produce chemically reactive metabolites; these drugs include aromatic amines (e.g., procainamide, dapsone, sulfadiazine, aminosalicylic acid, aminoglutethimide, sulfasalazine, practolol, acebutolol), hydrazines (e.g., hydralazine, isoniazid, phenelzine, hydrazine), or drugs containing a sulfhydryl or thiono group (e.g., propylthiouracil, methimazole, penicillamine, and captopril). Drugs characterized as hydantoin anticonvulsants (e.g., phenytoin, mephenytoin, ethosuximide, trimethadione) may also cause drug-induced lupus because of their similar reactive metabolites. The association between the production of reactive metabolites based on the biochemical structure of a drug and its potential to induce lupus is merely hypothesized. Lithium is associated with lupus but undergoes no metabolism at all.

RISK FACTORS

Risk factors for drug-induced lupus are listed in **Table 7-6** and are often specific to the causative agent. Patient characteristics that influence drug metabolism have been associated with drug-induced lupus.[19] In the past, investigators identified lupus diathesis as a risk factor for drug-induced lupus. However, this has not been proven.

Many reported cases of drug-induced lupus are in older patients (mean age = 62 years).[5,17,35,227] This may be because patients who take these drugs, typically prescribed for cardiac and other diseases, tend to be older.[17,27,35,253] However, cases of anticonvulsant-induced lupus have been reported most commonly in children.[19,20,75,262,264]

According to case reports published in the United States, white patients are six times more likely to be affected by drug-induced lupus as compared with black individuals.[6,20,21,35,265] The ratio of occurrence of idiopathic SLE in blacks versus whites is 2.7:1. However, this ratio is 0.3:1 for procainamide-induced lupus and 0.2:1 for hydralazine-induced lupus.[17]

Table 7-6 Risk Factors for Drug-Induced Lupus

- Certain HLA allele expression (HLA-DR2, HLA-DR4, HLA-DQB1)
- Duration of drug use (3 weeks to 2 years)
- Female sex
- High single dose or high cumulative dose of drug
- Older age (mean age, 62 years)
- Presence of null alleles for fourth component of complement (C4)
- Slow acetylator phenotype
- White race

HLA = human leukocyte antigen.

Idiopathic SLE occurs more commonly in females, with a reported female-to-male ratio of 9:1.[20] Conversely, drug-induced lupus tends to affect both sexes equally, although females may still be at a slightly increased risk; female-to-male ratios range from 1:1 to 1.6:1.[1,17,20,256-258,262,266] An exception is patients with minocycline-induced lupus, with which women are 14 times more likely than men to be affected.[1] It has been hypothesized that women may often have a higher risk of minocycline-induced lupus because of the estrogen-related increase of calcineurin activity causing enhanced T-cell activation.[267]

Many cases of drug-induced lupus occur after prolonged administration of the causative agent for 1 month or longer.[83] Drugs such as antiepileptics, antiarrhythmics (procainamide), and other medications (e.g., hydralazine, isoniazid, chlorpromazine) cause lupus in a dose-dependent manner.[5,17,19,35] This dose relationship may correlate to the accumulation of unacetylated drug in the body.[17,19] Hydralazine doses >200 mg/day or cumulative doses of more than 100 g have been associated with lupus-like syndrome.[20,265,268]

Certain drugs undergo acetylation to be inactivated. Patients who are slow acetylators often are at a higher risk of adverse effects from these drugs because of the potential for accumulation of the active drug. For instance, sulfasalazine is metabolized into sulfapyridine and 5-aminosalicylic acid; the sulfapyridine component is typically acetylated in the liver by the enzyme *N*-acetyltransferase 2 (NAT2). Individuals with a mutation on the *NAT2* gene have impaired enzyme function (“slow acetylators”) and present with higher concentrations of the active sulfapyridine component rather than its inactivated form.[126,269] Slow acetylators of procainamide experience lupus-like symptoms four times more rapidly than fast acetylators, and positive ANA tests develop at lower cumulative drug doses in slow acetylators than in fast acetylators.[227,270] Other drugs that are acetylated in the liver through NAT2 include hydralazine, isoniazid, and sulfonamides.[5,17,20,210,227]

The severity of hydralazine-induced lupus is greatly influenced by acetylator phenotype. One study reported that 60% of slow acetylators taking <400 mg of hydralazine had a positive ANA test, whereas 0% of fast acetylators taking the same dose of hydralazine showed positive serum ANA titers.[269] On the other hand, although the incidence of procainamide-induced lupus is higher in slow acetylators, the severity of procainamide-induced lupus is influenced minimally by acetylator type.[207,269] Because both fast and slow acetylators may experience procainamide-induced lupus, it has been hypothesized that a reactive, nonacetylated metabolite of procainamide may be responsible for the syndrome.[270] The influence of the acetylator phenotype is supported by the evidence that no cases of drug-induced lupus associated with the administration of the acetylated form of procainamide, *N*-acetylprocainamide, have been reported.[17,19] Acetylator phenotype is not necessarily a risk factor for lupus induced by all drugs reported to induce this disease; this risk factor is exclusive to certain drugs (Table 7-2). It is also important to note that acetylator status does not influence idiopathic SLE.[271]

Various HLA types, especially HLA-DR2 and DR4, are associated with SLE.[20] However, only HLA-DR4, which is associated with slow acetylation, has been shown to be strongly associated with hydralazine-induced lupus.[5] For example, in one study, 73% of patients with hydralazine-induced lupus had HLA-DR4.[208] The presence of a null allele for C4 is also a risk factor for drug-induced lupus.[51,225]

MORBIDITY AND MORTALITY

Drug-induced lupus usually resolves within weeks to months after discontinuation of the offending drug, although the ANA test may remain positive for months to years.[5,20] It is fatal only in extremely rare circumstances, usually as a result of kidney failure.[5] The psychosocial impact of a drug-induced lupus diagnosis is not as severe as that of idiopathic SLE due to the relatively shorter duration and better prognosis associated with drug-induced lupus. Healthcare utilization is short-term for drug-induced lupus but, with either condition, emotional support, symptomatic treatment, and intentional patient involvement to gather information for an accurate assessment are vital to a timely diagnosis and appropriate treatment.[272]

PREVENTION

Monitoring parameters for prevention and detection of drug-induced lupus are presented in **Table 7-7**. Drug-induced lupus is an idiosyncratic drug reaction that may not be explained by the known pharmacologic actions of the specific drug. To prevent drug-induced lupus, drugs known to cause the lupus-like syndrome should be avoided. However, avoidance of certain drugs may not be an option in many medical circumstances. The lupus-inducing potential of only a select number of drugs has been substantiated with results from prospective studies. The potential for other drugs to cause lupus is supported only by spontaneous, and often single, case reports. As a routine screening process, baseline serum ANA titers should be determined when initiating a medication documented to induce lupus.[35] Periodic ANA testing should be initiated based on clinical judgment, remembering that serum ANA titers alone are not diagnostic of drug-induced lupus. A common recommendation is to obtain a complete blood count, ANA titer, and ESR every 3 months in a patient receiving a drug with the potential to cause lupus.[20] Periodic assessment of constitutional signs and symptoms associated with the syndrome helps guide the clinical decision to continue or discontinue therapy with the implicated drug.

Table 7-7 Approaches to Help Prevent Drug-Induced Lupus

Monitor the following at baseline and every 3 months during therapy:

- Serum antinuclear antibody titers
- Complete blood count
- Erythrocyte sedimentation rate
- Signs and symptoms of drug-induced lupus

There are no data to support cross-sensitivity between medications implicated in drug-induced lupus; therefore, it is not possible to say with certainty that patients experiencing drug-induced lupus while taking one medication will develop the same reaction to another potential lupus-causing drug. However, careful clinical decision making is necessary when considering treatment with these medications. Patients should be followed carefully and appropriate baseline testing should be performed to ensure patient safety during the course of treatment.

MANAGEMENT

Strategies for managing drug-induced lupus are presented in **Table 7-8**. Symptoms of drug-induced lupus do not subside with continued administration of the offending agent, although they are reversible on discontinuation of therapy.[19,227,231] Therefore, discontinuation of the offending drug is required. Clinical and laboratory findings associated with drug-induced lupus typically disappear within weeks. Rarely, clinical and laboratory findings may take years to resolve after the termination of therapy with the lupus-inducing drug.[5,19,20,126,262] Although symptoms often resolve quickly, serum ANA titers may fall gradually over several months to 2 years.[5,35,51] Clinical symptoms of lupus do not develop in most asymptomatic patients with positive ANA titers, and discontinuation of therapy is not required in these cases.[8,51]

Table 7-8 Management of Drug-Induced Lupus

Sign/Symptom	Management
Positive antinuclear antibody only	Continue drug if asymptomatic
Any lupus-like symptoms	Discontinue drug immediately
Persistent constitutional symptoms and/or musculoskeletal symptoms	Discontinue drug immediately; treat symptoms with aspirin or nonsteroidal anti-inflammatory drugs
Cardiovascular (e.g., pleurisy, pericarditis), kidney involvement (e.g., increasing proteinuria/creatinine, active urinary sediment), neuropsychiatric symptoms	Discontinue drug immediately Initiate low-dose corticosteroids (e.g., prednisone 0.5–1.0 mg/kg daily) tapered over 1 week to several months; combine with another immunosuppressant (e.g., azathioprine, mycophenolate mofetil, cyclophosphamide, methotrexate) for refractory cases requiring long-term steroid use Initiate or change/escalate antihypertensive therapy if at least two blood pressure readings over 3 months include systolic blood pressure readings >130 mm Hg or diastolic blood pressure readings >80 mm Hg
Skin and joint manifestations, and constitutional symptoms including fever, malaise, and fatigue	Initiate hydroxychloroquine at 200 mg twice daily and continue indefinitely

Patients often improve dramatically without treatment. Patients experiencing musculoskeletal and mild constitutional symptoms (e.g., pyrexia, arthralgia, myalgia) may be treated with anti-inflammatory agents such as aspirin and nonsteroidal anti-inflammatory drugs if there are no contraindications to their use.[17,19,20,227,231,273] However, patients presenting with more severe symptoms (e.g., pleurisy, pericarditis, kidney involvement, neuropsychiatric) require treatment with empirical, short-term low-dose systemic corticosteroids (e.g., prednisone 0.5–1.0 mg/kg/day) tapered over 1 week to several months, which may require an additional immunosuppressant and/antihypertensive therapy, if refractory.[5,16,17,19,20,227,256,257,262,273-275] Patients presenting with drug-induced lupus-associated skin manifestations have been treated with antimalarial agents (i.e., chloroquine–hydroxychloroquine).[5,231,273,275] Several case reports describe rechallenge of the offending agent; lupus symptoms promptly reappeared on reinitiation of the drug.[39,227]

INFORMATION FOR PATIENTS

When patients are initiated on a drug that is strongly associated with drug-induced lupus, the healthcare professional should counsel the patient regarding the fact that symptoms of arthralgia or arthritis may occur at any time during the therapy—up to and including 2 years after the first dose. Regardless of whether or not the patient has an arthritis-related medical condition before the initiation of the drug, symptoms of fever, malaise, and skin manifestations of unknown origin should be reported promptly. The patient should also be counseled regarding other specific symptoms associated with the implicated drugs (e.g., pulmonary symptoms with procainamide, symptoms of hepatotoxicity with minocycline) and educated on sun avoidance. The healthcare professional must educate the patient regarding the importance of reporting symptoms because of (1) the progression of the syndrome if ignored, and (2) the reversibility of the syndrome on cessation of therapy with implicated drug.

CHAPTER 8

Photosensitivity

Julie M. Koehler

Drug-induced photosensitivity is a term used to describe an undesirable pharmacologic reaction to ultraviolet radiation (UVR), which is categorized as either ultraviolet A (UVA) or ultraviolet B (UVB).[1-3] Although UVB radiation causes erythema, UVA radiation is largely responsible for tanning, photoaging, and drug-induced photosensitivity.[4] Drug-induced photosensitivity reactions are quite common today as a result of an increased number of photosensitizing chemicals found in many drug products.[1] Drug-induced photosensitivity reactions are typically classified as either phototoxic or photoallergic.

CAUSATIVE AGENTS

Several drugs and drug classes, including both systemic drugs and topically applied compounds, have been implicated in causing clinically significant photosensitivity reactions (**Table 8-1**).[5-368] Drug classes that have been reported to cause phototoxic reactions include, but are not limited to, nonsteroidal anti-inflammatory drugs (NSAIDs), tetracyclines, sulfonamides, fluoroquinolones, phenothiazines, and diuretics.[2-371] Drug classes that may cause photoallergic reactions include, but are not limited to, tetracyclines, sulfonamides, diuretics, phenothiazines, and antihistamines.[369-371] Furthermore, many of the drugs within these classes have been linked to the development of both types of photosensitivity (i.e., phototoxic and photoallergic) reactions.

EPIDEMIOLOGY

Although there are many case reports describing drug-induced photosensitivity reactions, it is challenging to estimate the true incidence of such reactions, given the difficulty in distinguishing between sunburn and a mild drug-induced photosensitivity reaction and the resultant potential for bias or inaccuracy in reporting. This is further confounded by patients' ability to control the occurrence of photosensitivity reactions by taking protective action against sunlight exposure.[370] Although the exact incidence of drug-induced photosensitivity in the general population has not been defined, results from a retrospective review from a skin-treatment referral center in Singapore indicated that 11.3% of all cases of photodermatoses were the result of drug-induced photosensitivity.[372] A more recent review by Dawe et al. reports an incidence of drug-induced photosensitivity ranging between 2% and 15% in patients who were referred to tertiary photodermatology centers.[373] In general, drug-induced phototoxic reactions occur more commonly than photoallergic reactions, and phototoxic reactions may occur in almost any person who receives a sufficiently high dose of the offending agent coupled with enough exposure to UVR.[374,375] The occurrence of drug-induced phototoxicity reactions are, therefore, dependent on the concentration (or amount) of the sensitizing agent (drug) and the amount of light exposure. The recorded incidence, where known, of photosensitivity associated with the administration of specific drugs is included in Table 8-1.[5-368]

Table 8-1 Agents Implicated in Drug-Induced Photosensitivity[5-368]

Drug	Incidence	Level of Evidence[a]
Acebutolol[5]	NK	C
Acetazolamide[6]	NK	C
Alectinib[7]	9.9%	A
Alfalfa[8]	NK	C
Alitretinoin[9]	NK	C

Alprazolam[10,11]	NK	C
Amantadine[12]	NK	C
Aminolevulinic acid[13,14]	NK	C
Amiodarone[15-22]	3–10%	B
Amitriptyline[23,24]	NK	C
Amlodipine[25,26]	NK	C
Anagrelide[27]	NK	B
Aripiprazole[3,28]	0.1–1%	A
Atovaquone–proguanil[29]	NK	C
Azathioprine[30]	NK	B
Benazepril[31]	<1%	A
Benzocaine[32]	NK	C
Bergamot oil[33]	NK	B
Bexarotene[34]	NK	C
Bicalutamide[35]	NK	C
Bishop’s weed[36]	NK	C
Bitter orange[37]	NK	B
Calcipotriene[38]	NK	C
Canagliflozin[38]	0.2%	A
Captopril[39]	NK	C
Carbamazepine[40]	NK	C
Carvedilol[41]	0.1–1%	A
Cefazolin[42]	NK	C
Ceftazidime[43]	NK	C
Celecoxib[44]	NK	C
Cetirizine[3]	<2%	A
Chlordiazepoxide[45,46]	NK	C
Chlorella[47]	NK	C
Chloroquine[48]	NK	C
Chlorothiazide[49-51]	NK	C
Chlorpromazine[52-55]	NK	C
Chlorpropamide[56]	NK	C

Chlorthalidone[57]	NK	C
Chrysanthemum[58-63]	NK	B
Ciprofloxacin[3,64-67]	<1%	A
Clioquinol[68]	NK	C
Clofazimine[69]	<1%	B
Clomipramine[70]	NK	C
Clopidogrel[71]	NK	C
Clozapine[72]	NK	C
Coal tar[73-75]	NK	B
Cobimetinib[76]	47%	A
Crizotinib[77]	NK	C
Cyclobenzaprine[78]	<1%	A
Cyproheptadine[79]	NK	C
Dacarbazine[3,80]	<0.1%	B
Dantrolene[81]	NK	C
Dapsone[82,83]	NK	C

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Incidence reported is for topical gel only.

[c] Incidence varies according to type of cancer being treated.

[d] Incidence reported is for topical foam only.

MECHANISMS

Photosensitivity reactions can be classified according to the underlying mechanism or pathogenesis of the reaction. Specifically, photosensitivity reactions are the result of either phototoxicity or photoallergy. Phototoxic reactions represent the most common form, and photoallergic reactions are generally uncommon.

Phototoxic reactions are a type of nonimmunologic reaction. During phototoxic reactions, the drug, after ingestion or topical application, is believed to potentiate solar energy by acting as a chromophore (i.e., a chemical group that absorbs light at a specific frequency and imparts color to a molecule), causing absorption of ultraviolet (UV) light and yielding damage to skin tissues, including molecular and cellular damage as well as potential generation of reactive oxygen species.[1] In contrast to photoallergic reactions, drug-induced phototoxic reactions typically occur on first exposure to the drug and are often dose-related.[1,2,369,375] **Figure 8-1** illustrates the underlying mechanism of drug-induced phototoxic reactions.[4,369,371,374]

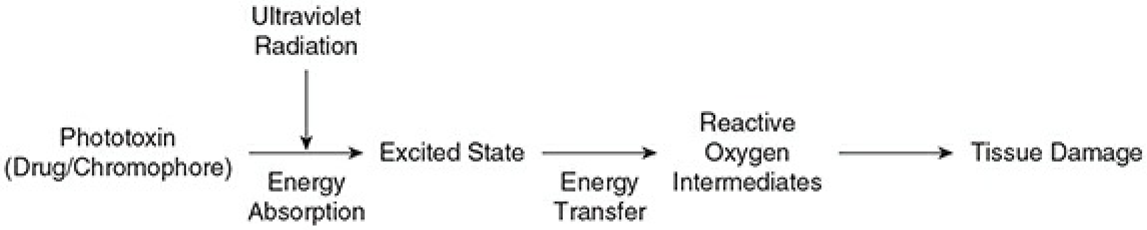

FIGURE 8-1 Mechanism of Drug-Induced Phototoxicity[371]

Unlike phototoxic reactions, drug-induced photoallergic reactions are the result of an immunologic response. The proposed mechanism of photoallergic reactions is that of a type IV cell-mediated hypersensitivity response (i.e., a delayed reaction, mediated by T cells rather than by antibodies, as opposed to a type I reaction, which involves IgE-mediated histamine release from mast cells and basophils; a type II reaction, which involves IgG or IgM antibodies bound to cell surface antigens; or a type III reaction, which involves deposition of circulating antigen-antibody immune complexes).[1,369,374] Specifically, it is postulated that when UV light reacts with either the drug or the drug's metabolites in the skin, a structural change in the drug occurs such that it behaves as a hapten (i.e., a small, separable part of an antigen that reacts with an antibody and is only capable of antibody production when combined with a carrier protein), which then combines with proteins in the skin (a tissue antigen) to form a hapten-protein complex (complete antigen).[1,374] On subsequent exposure to the drug, a hypersensitivity (photoallergic) response is elicited. Once the patient is "sensitized" to the drug, subsequently only minimal amounts of drug exposure are required to produce a photoallergic reaction.[1] In general, photoallergic reactions occurring in sensitized patients are not dose-dependent.[2] Because photoallergic reactions involve the immune system, there is typically a delay between the time of drug exposure and the onset of the skin eruption.[1] **Figure 8-2** illustrates the underlying mechanisms of drug-induced photoallergic reactions.[371,374]

FIGURE 8-2 Mechanism of Drug-Induced Photoallergy[371]

Although the general underlying mechanisms of drug-induced photoallergy and phototoxicity are well-described in the literature, information regarding the exact mechanisms of photosensitivity associated with specific drug classes and individual agents are not as well understood. **Table 8-2** summarizes possible underlying mechanisms of drug-induced photosensitivity reactions for selected agents.

Table 8-2 Mechanisms of Drug-Induced Photosensitivity

Drug Classes	Mechanism(s)
Diuretics	Dissociation of chlorine substituent on ultraviolet light exposure, causing free radical formation[370]
Nonsteroidal anti-inflammatory drugs	Decarboxylation reaction on ultraviolet light exposure, causing free radical formation[370,371,375]
Phenothiazines	Dissociation of chlorine substituent on ultraviolet light exposure, causing free radical formation[370] Complement, proteases and histamine may also play a role[371]

Photosensitizing agents	Free radical formation on ultraviolet light exposure
Psoralens	Possible alteration of DNA synthesis and direct inflammatory effect, leading to increased melanin production and an erythemogenic effect[371]
Tetracyclines	Oxidative reaction on ultraviolet light exposure, causing free radical formation Polymorphonuclear cells and complement may also serve as inflammatory mediators[371]

DNA = deoxyribonucleic acid.

DIURETICS AND PHENOTHIAZINES

Diuretics such as hydrochlorothiazide, chlorthalidone, and furosemide and phenothiazines such as chlorpromazine and promethazine contain chlorine substituents within their chemical structures. It has been postulated that UV light exposure causes dissociation of the chlorine substituents, which is believed to lead to free radical formation, producing a photosensitivity reaction.[370] Complement, proteases, and histamine may also play a role in phenothiazine-induced phototoxicity, however, suggesting a nonoxidative mechanism.[371]

NSAIDs

Many NSAIDs have been reported to cause photosensitivity reactions. Within the NSAID class, drugs such as ketoprofen, naproxen, and nabumetone, which contain a 2-aryl propionic acid group, are thought to be the most photoactive.[370,371,375] It is believed that a decarboxylation reaction occurs on exposure to UV light, resulting in free radical formation and a subsequent photosensitivity reaction. NSAIDs lacking the 2-aryl propionic acid group, such as ibuprofen, have also been reported to cause photosensitivity, however, via a less well-understood mechanism.[370,375]

ANTIBACTERIALS

Many antibacterial agents are known to elicit a high degree of photosensitivity. Tetracyclines, fluoroquinolones, and sulfonamides are among the classes that are most commonly implicated.[370,373,375] Within the tetracycline class in particular, oxidative reactions involving free radical formation are believed to play a role.[371] Polymorphonuclear cells and complement have also been identified as potential inflammatory mediators involved in the mechanism of tetracycline-induced photosensitivity.[371]

PSORALENS

Psoralen derivatives, such as methoxsalen, represent a unique class of drugs in that their inherent photosensitizing mechanism is used therapeutically in combination with controlled UV light exposure to produce a melanogenic effect for the treatment of disorders such as idiopathic vitiligo.[371] Thus, the photosensitizing potential of such agents is a known and, for the most part, intended effect. Methoxsalen, when activated by UVA light, becomes highly erythemogenic and melanogenic. Although the precise mechanism by which these agents induce phototoxic reactions is not completely known, it is believed that psoralen-induced phototoxicity involves nonoxygen-dependent pathways and may be linked most closely to the alteration of deoxyribonucleic acid (DNA) synthesis and direct induction of an inflammatory skin reaction to enhance melanin formation.[371]

PHOTOSENSITIZING AGENTS

Porfimer (indicated for palliative treatment in esophageal cancer, for endobronchial non-small cell lung cancer, and for high-grade Barrett esophageal dysplasia) and verteporfin (used for neovascularization associated with age-related macular degeneration, pathologic myopia, or presumed ocular histoplasmosis) represent drugs that are used therapeutically because of their known photosensitizing properties. Both of these agents are used in photodynamic therapy for which UV light exposure is required for pharmacologic activation. On exposure to UV light, these photosensitizers become activated in the presence of oxygen, and free radicals are generated, enhancing the potential for phototoxicity.[371]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Classic signs and symptoms associated with drug-induced photosensitivity are listed in **Table 8-3**.[369] Symptoms of drug-induced photosensitivity reactions are very similar to those of a sunburn. Typical photosensitivity reactions may result in the development of erythema, edema, and papules, and in severe cases, may also progress to the development of plaque-like urticarial lesions and possible vesicle formation.[1,369] When differentiating between photosensitivity and other types of skin eruptions, clinicians should note that photosensitivity eruptions classically manifest on areas of the skin that are most routinely exposed to sunlight (e.g., nose, cheeks, tops of the ears, neck, forearms, backs of the hands).[1,369] In general, sharp lines of demarcation between sunlight-exposed and uninvolved skin are noted.[369] In some cases, however, skin eruptions can appear on areas of the skin that receive little to no sun exposure and may be generalized over the entire body. In general, while differentiation between drug-induced photosensitivity and other adverse skin reactions to sunlight may be somewhat challenging (**Table 8-4**), differentiation between cases of drug-induced phototoxicity and photoallergy can also be difficult, given that many drugs have been implicated in causing both types of reactions.[2,371] Differences between the characteristics of phototoxic and photoallergic reactions are highlighted in **Table 8-5**.[2,371] Examples of the clinical appearance of drug-induced phototoxic and photoallergic reactions are presented in **Figure 8-3**.

Table 8-3 Signs and Symptoms Associated with Drug-Induced Photosensitivity[369]

- Edema
- Erythema
- Erythroderma
- Hyperpigmentation
- Pain
- Papules
- Petechiae
- Pruritus
- Scaly patches
- Scarring
- Swelling
- Vesicles
- Wheals

Table 8-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Photosensitivity[369]

- Actinic prurigo
- Allergic contact dermatitis
- Epidermolysis bullosa
- Epidermolysis bullosa acquisita
- Erythropoietic protoporphyria
- Hydroa vacciniforme
- Irritant contact dermatitis
- Lichen planus
- Plant-induced photosensitivity reaction (phytophotodermatitis)
- Polymorphic light eruption
- Solar urticaria
- Sunburn
- Systemic lupus erythematosus (subacute cutaneous lupus erythematosus)

Cases of drug-induced phototoxic reactions are associated with a much more rapid onset (e.g., within 30 minutes to several hours after exposure to UV light) than those of drug-induced photoallergy.[2] In general, phototoxic reactions are less severe than photoallergic reactions and resemble an exaggerated sunburn.[2]

Phototoxic reactions are associated with erythema and pain, and occasionally may progress to blistering and vesicle formation.[369] Within several days of the onset of the reaction, the damaged skin may begin to desquamate (i.e., peel off in scales).[369]

Table 8-5 Differentiating Characteristics of Phototoxicity and Photoallergy[2,371]

Characteristic	Phototoxicity	Photoallergy
Frequency of occurrence	Common	Uncommon
Mechanism	Nonimmune-mediated	Immune-mediated
Onset after exposure to drug and sunlight	Immediate (minutes to hours); may occur after single exposure to drug	May be delayed (hours to days); usually occurs after more than one exposure to drug
Distribution	Usually confined to exposed skin	May affect both exposed and unexposed skin
Potential for pigmentary changes	High	Low
Dose-dependency	Yes	No
Potential for cross reactivity	No	Yes
Potential for persistent light reaction	No	Yes

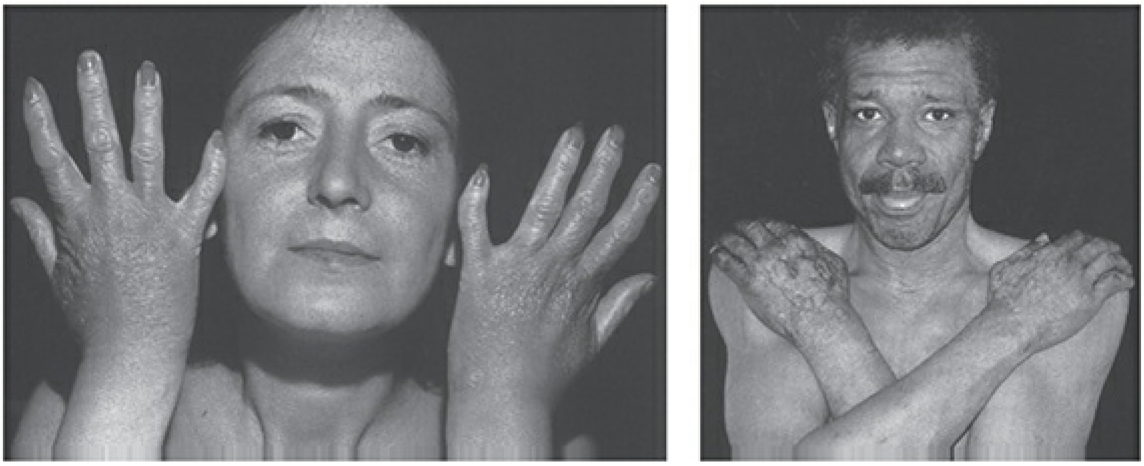

FIGURE 8-3 Drug-Induced Phototoxicity and Photoallergy

The photo on the left depicts a case of drug-induced phototoxicity secondary to demethylchlortetracycline use for treatment of acne. The woman was wearing a hat that protected her face and neck from sunlight exposure, but her hands were exposed to sunlight while holding a railing at a sporting event. The photo on the right depicts a case of drug-induced photoallergy secondary to trimethoprim–sulfamethoxazole use for *Pneumocystis jiroveci* pneumonia prophylaxis. Eczema and hyperpigmentation of the sun-exposed areas are noted. Photos reprinted with permission from Wolff K, Johnson RA, Suurmond D. *Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology: Common and Serious Diseases*. 5th ed. New York, NY: McGraw-Hill; 2005:226-69. (See color section.)

In some cases, epidermal thickening, elastosis, telangiectasia, and pigmentary changes (hyperpigmentation or hypopigmentation) may occur in association with phototoxic reactions.[1] Pigmentary changes occur commonly (4–9%) as a manifestation of photosensitivity in patients receiving long-term, high-dose amiodarone therapy.[371,376-381] Specifically, a blue-gray discoloration commonly develops on areas of the skin that are subjected to unprotected light exposure because of the deposition of amiodarone and its metabolites within the dermis.[371,378,379,381]

The skin damage that occurs in phototoxic reactions is typically confined to areas of exposed skin only. However, occasionally the nails may also be affected. This phototoxic effect is a well-known phenomenon known as photo-onycholysis (i.e., separation of the nail from the distal nailbed in conjunction with sun exposure and simultaneous drug use).[2,4,369] Histologically, dermal edema (swelling of the skin), dyskeratosis (aberrant development of the epidermis with abnormal keratinization), and keratinocytic necrosis (injury to keratinocytes, the predominant cell in the epidermis) may be observed.[4,369]

Cases of drug-induced photoallergic reactions are typically associated with an onset ranging from 24 to 48 hours to up to 14 days after initial exposure to the sun. The initial eruption is usually described as a papulovesicular, intensely pruritic, eczematous dermatitis.[369] In some cases, the rash may involve lichenoid, urticarial, bullous, or purpuric lesions. Histopathologic findings in cases of drug-induced photoallergy are typically similar to those found in cases of contact dermatitis.[1] In general, photoallergic reactions involve only areas directly exposed to the sun, but in severe cases, these reactions may also affect areas that are normally protected from UV light. It is important to note that after discontinuation of therapy with the offending agent, the clinical effects of drug-induced photoallergy may persist for some time. Over time, the eruptions may even become hyperpigmented or hypopigmented.[371]

If the diagnosis of a drug-induced photoreaction remains uncertain after obtaining a thorough history and conducting a full skin exam, photopatch testing may be useful and may further aid in the identification of the offending agent. During photopatch testing, template test sites are exposed to increasing doses of UVA while the patient is taking the suspected drug.[382] In patients with a phototoxicity or photoallergy secondary to a drug, the UVA minimal erythema dose (MED, or the minimum UVA dose that produces a clearly marginated erythema in the irradiated site 24 hours after a single exposure) is significantly lower than the MED for a normal individual of the same skin type. Once the drug is excreted and eliminated from the skin, repeat UVA photopatch testing yields an increase in the MED result.[382]

RISK FACTORS

Several risk factors may increase a person's susceptibility to drug-induced photosensitivity reactions (**Table 8-6**).[2,369,371,374] For any patient who is taking a known photosensitizing agent, use of sunscreens and protective clothing is warranted to minimize the risk of a photosensitivity reaction. It should be noted, however, that occasionally sunscreens themselves can act as photosensitizing agents. Sunscreens containing para-aminobenzoic acid (PABA) contain a sulfa moiety, which may aggravate photodermatitis in sensitized individuals. Although PABA-based sunscreens became widely available in the 1970s, the use of PABA as an ingredient in sunscreens today is much less common, and the majority of commercially available products are promoted as "PABA-free." Padimate O (also known as octyl dimethyl-PABA) is a PABA ester that is chemically similar to PABA but is not as irritating and today can be found in some sunscreen products, including lip balms. In general, sunscreens containing PABA or PABA esters should be avoided in susceptible individuals.[369,371,375]

Table 8-6 Risk Factors for Drug-Induced Photosensitivity Reactions[2,369,371,374]

- Drug–drug interactions
- High drug dose (phototoxic reactions only)
- Immunocompromised state
- Lack of protection against sunlight exposure
- Light skin (types I and II)/fair complexion
- Use of sunscreen products containing PABA or PABA esters (e.g., padimate O)

PABA = para-aminobenzoic acid.

In cases of phototoxicity, the dose of the photosensitizing agent itself may be a risk factor. For example, dose-related increases in the incidence of light eruptions have been reported in association with doxycycline.[383] Reduction of the dose of the offending agent during phototoxic reactions has been shown to yield symptom and reaction resolution in some cases, supporting the theory that dose can be an important risk factor.[384,385]

In cases of photoallergy, the patient's immune status may be an important risk factor. For example, human immunodeficiency virus (HIV) photodermatitis is estimated to occur in approximately 5% of HIV-positive patients with CD4 T lymphocyte counts of 50 cells/µL or lower, with the risk for development increasing as CD4 T lymphocyte counts decline.[2,386-389]

Drug–drug interactions involving photosensitizing agents may play a role in photosensitivity. Concomitant administration of photosensitizing agents such as porfimer, verteporfin, or psoralens (e.g., methoxsalen) and other agents reported to cause photosensitivity reactions (Table 8-1), such as tetracyclines, phenothiazines, diuretics, sulfonamides, NSAIDs, and others may produce additive photosensitizing effects, thereby increasing the potential for a photosensitivity reaction. In cases of amiodarone-induced photosensitivity, coadministration of pyridoxine has been demonstrated to worsen the photosensitivity reaction, possibly because of a metabolic effect resulting in damage to the skin's structural integrity.[15,381] More specifically, amiodarone is believed to induce phototoxic damage when, following the absorption of a photon, an excited (triplet) state is created, and the excited molecules then interact with a biological target to form a radical species. This species is then susceptible to interaction with molecular oxygen, leading to peroxidation.[263,390] Although the mechanism is not fully understood, pyridoxine enhancement of amiodarone phototoxicity has been demonstrated in vitro through induction of photosensitizing enzyme processes by pyridoxal phosphate, a catalytically active form of vitamin B6.[263,390] Evidence of this has also been suggested in one small randomized, double-blind, placebo-controlled trial.[15] Thami et al. reported a reactivation of photodermatitis caused by the concomitant administration of haloperidol and methotrexate in a patient with psoriasis.[391] Although both drugs have been reported to cause photosensitivity reactions, a possible drug interaction, in which haloperidol likely interfered with tryptophan metabolism, was suggested to play a role in the development of the adverse reaction.[391] With respect to phototoxicity, for which the dose of the drug may be an important factor, any drug interaction that may cause a significant increase in the plasma concentration of the photosensitizing drug may contribute to the development of photosensitivity reactions.

MORBIDITY AND MORTALITY

In general, drug-induced photosensitivity reactions rarely involve significant morbidity or mortality (although voriconazole-induced photosensitivity has been linked to squamous cell carcinoma).[359,392-396] Most reactions are reversible after discontinuation of the offending agent.[2] In some cases, complete resolution of a drug-induced photosensitivity reaction may require weeks to months. In 5–10% of patients who experience photoallergy, however, a chronic condition known as persistent light reaction (PLR) may develop; this is also occasionally described as chronic actinic dermatitis.[397] In such patients, the photosensitivity reaction persists after drug discontinuation, and relapse of the reaction occurs on minimal exposure to UV light in the absence of the offending agent. Although PLR may occur in patients sensitized to systemic photosensitizing agents, it is believed to occur more commonly in patients sensitized to topical photosensitizers.[2]

Table 8-7 Approaches to Help Prevent Drug-Induced Photosensitivity[369,400]

- Avoid sunlight
- Use broad-spectrum sunscreens that block both ultraviolet A and B sunlight (minimum sun protection factor of 30[a])
- Avoid sunscreens containing PABA
- Use protective clothing (e.g., wide-brimmed hats, sunglasses, and long-sleeved shirts)
- Use dietary supplements containing antioxidants[b]

PABA = para-aminobenzoic acid.

[a] Although the U.S. Food and Drug Administration recommends a minimum sun protection factor of 15, the American Academy of Dermatology currently recommends a minimum of 30.

[b] Further study is needed to confirm the efficacy of this method.

PREVENTION

Some methods for preventing drug-induced photosensitivity reactions are listed in Table 8-7.[369,375] In the case of both photoallergic and phototoxic reactions, the best means of prevention includes both the avoidance of sunlight and the use of broad-spectrum sunscreens that block both UVA and UVB sunlight.[369,375,398-400] Because of their potential to cause or aggravate photodermatitis, sunscreen products containing PABA or PABA esters should specifically be avoided. For patients who are receiving photodynamic therapy with agents such as porfimer and verteporfin, it is important to note that opaque sunscreens such as zinc oxide should be used, as nonopaque sunscreens are ineffective for prevention of the photosensitivity induced by these agents.[256,354] Further, it should be noted that sunscreen protection may not always be sufficient to prevent drug-induced photosensitivity reactions. Therefore, the use of protective clothing may also be necessary to prevent adverse reactions to light exposure.

Based on the underlying mechanism of photosensitivity reactions, it has also been suggested that dietary supplementation with antioxidants may help prevent adverse cutaneous photoreactions.[370,398] However, further study is needed to validate this method of prevention.

MANAGEMENT

The appropriate treatment of drug-induced photosensitivity reactions depends to some degree on the type of reaction (i.e., photoallergic or phototoxic). Treatment of patients with phototoxic reactions is similar to that of patients with routine sunburn. Discontinuation of the offending drug often accelerates resolution. In some cases of phototoxicity, reducing the dose of the offending agent (rather than drug discontinuation) may result in resolution of the reaction.[69,371,375,398] In cases of amiodarone-induced photosensitivity in which blue-gray discoloration of the skin has occurred, dose reduction has resulted in gradual disappearance of the pigmentary changes.[380] Systemic corticosteroids are not effective for the management of drug-induced phototoxicity.[1,398,399] Similarly, topical antihistamines have also been shown to be ineffective.[1]

For patients experiencing a photoallergic reaction, both antihistamines and corticosteroids may be prescribed to assist with symptom relief. Oral prednisone in doses of 1 mg/kg/day administered as a short burst (e.g., 3–10 days) or tapered over the course of 3 weeks has been shown to be highly effective in symptomatic patients suffering from photoallergy.[1,369] Topical corticosteroids (e.g., betamethasone valerate 0.1% cream) or NSAIDs (e.g., indomethacin 25 mg three times daily or ibuprofen 400 mg four times daily) may help to reduce pain and inflammation.[369] The use of NSAIDs or corticosteroids should be avoided, however, in cases where such medications have been identified as the potential causative agent of the photoreaction (refer to Table 8-1 for specific NSAIDs and corticosteroids that have been reported to cause photosensitivity). In photoallergic reactions, discontinuation of the offending drug is almost always necessary.[2,371,375] For both types of photosensitivity reactions, the use of ice packs or cold water compresses may occasionally provide symptomatic relief.[369] Treatment options that may be employed in the management of photosensitivity reactions are listed in **Table 8-8**.[1,2,369,399]

Table 8-8 Treatment Options for Drug-Induced Photosensitivity[1,2,369,371,398-400]

- Discontinuation of the offending drug
- Reduction in dose of the offending drug[a]
- Nonsteroidal anti-inflammatory drugs
- Topical corticosteroids[b]
- Antihistamines[b]
- Systemic corticosteroids[b]
- Ice packs or cold water compresses

[a] May be effective only in certain cases of phototoxicity. Photoallergy reactions require discontinuation of the offending agent.

[b] Only shown to be effective in cases of photoallergy.

INFORMATION FOR PATIENTS

Patients for whom medications that have been reported to cause photosensitivity reactions are prescribed should be informed of the potential for this adverse effect prior to the initiation of therapy. During the course of therapy with the potentially photosensitizing agent, patients should be encouraged to avoid excessive exposure to sunlight, particularly from the hours of 10:00 a.m. to 4:00 p.m. and especially in the absence of protection against UV light. The patient should wear protective clothing (e.g., wide-brimmed hats, sunglasses, long-sleeved shirts) and use broad-spectrum sunscreens with a minimum sun protection factor of 30 (especially for patients with light, fair, pale, or albino skin tones; for patients with olive, brown, or black skin tones, a minimum sun protection factor of 15 may be sufficient) throughout the duration of therapy.[369,400] Zinc oxide and titanium dioxide provide a physical barrier that reflects and scatters the full spectrum of UVR; therefore, sunscreens containing these agents may provide the best protection against sunlight exposure. Although the majority of commercially available sunscreens today are marketed as “PABA-free,” consumers should be aware of sunscreens containing PABA or PABA esters, such as padimate O, and such products should generally be avoided in sensitized patients because of the potential to aggravate or worsen photodermatitis.[371,369]

CHAPTER 9

Alopecia, Hirsutism, and Hypertrichosis

Kristine E. Keplar

ALOPECIA

Alopecia is hair loss due to a disturbance of the hair growth cycle and may be manifested as complete or partial hair loss. Although the scalp is most often involved, the disorder can affect all hair-bearing areas of the body.[1-3] Most cases are caused by androgenetic alopecia, also known as male pattern baldness, secondary to hormonal and genetic factors. A relatively small percentage of alopecia cases are drug-induced.[4] Although drug-induced alopecia is not an extremely common event, it is quite distressing to the patient and, therefore, important to recognize.[5]

The three phases of hair growth are anagen, catagen, and telogen (**Figure 9-1**).[6-8] The anagen, or growth, phase is the most active phase of the growth cycle and lasts from several months to years. During this phase, the hair follicle produces hair continuously. Intense mitotic activity occurs, and follicles are highly susceptible to noxious events.[6] The catagen cycle, or transition period, lasts only 1–2 weeks.

During this phase, the inferior portion of the hair follicle significantly thins. The third and final phase of hair growth is the telogen, or resting, phase. This phase usually lasts 2–4 months, after which the follicle re-enters the anagen phase. At any given time, 80–90% of the follicles of the typical scalp are in the anagen phase, and 10–15% of follicles are in the telogen phase. Hair is shed during the telogen phase; telogen follicles usually shed between 30 and 100 hairs daily.[6,8,9] Follicles in the telogen and catagen phases, unlike those in the anagen phase, typically are not sensitive to noxious agents, such as cancer chemotherapy drugs, because of their inconsistent mitotic and metabolic activity.[6]

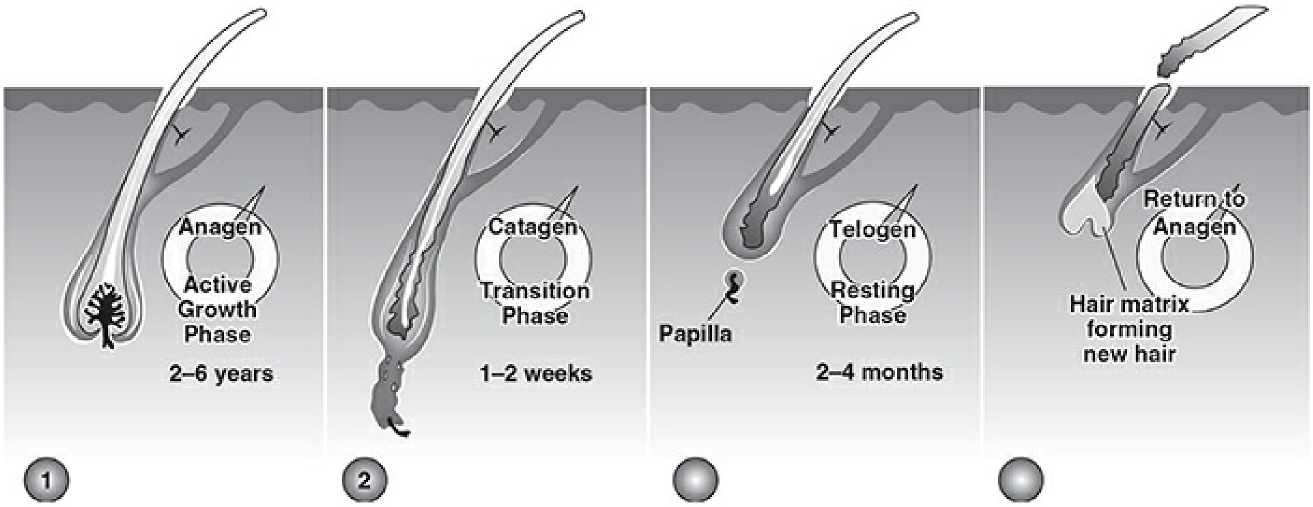

FIGURE 9-1 Diagram of the Hair Growth Cycle

During the normal hair cycle, the active growth phase (anagen) can last from 2 to 6 years. This is followed by a short transition phase (catagen), which lasts 1–2 weeks, and then by a resting phase (telogen), lasting 2–4 months. The hair is then shed, the anagen phase begins again, and a new hair is developed.[6-9]

Androgenetic alopecia, or male pattern baldness, is hair thinning that occurs in an M-shaped pattern, during which hair loss occurs on the crown and temple areas of the head but spares the back and sides of the head. It is termed *androgenetic alopecia* because it generally follows the distribution of androgen-sensitive hair follicles. Androgenetic hair loss is often familial and is thought to involve a physiologic process incited in genetically predisposed hair follicles under the influences of androgens. Drugs with androgenic activity can also induce this type of hair loss.[10-13]

Alopecia areata, an autoimmune inflammatory disease, is another type of alopecia that includes patchy hair loss, complete loss of scalp hair, or complete loss of scalp and body hair. Alopecia areata has been postulated to have an autoimmune pathogenesis involving inflammatory cytokines, including tumor necrosis factor alpha (TNFα). Alopecia areata is very rare, and only a few drugs have been associated with it. At this time, the precise pathogenesis of drug-induced alopecia areata has not been elucidated, but it is thought to involve the person's own immune system, which attacks healthy hair follicles by mistake.[13-17]

CAUSATIVE AGENTS

The primary medications that may induce alopecia are anticoagulants, androgenetic agents, hormone therapy, psychotropic drugs, thyroid medications, antiretroviral drugs, and cancer chemotherapy agents.[3,6,11,18] Drugs known to induce alopecia are listed in **Table 9-1**.[18-169]

ANTICOAGULANTS

Heparin and heparinoid drugs primarily affect scalp hairs. Hair loss usually occurs approximately 3 months after the initiation of treatment. In one report, the onset of hair loss varied from 1 week to 3 months after the last dose of heparin.[170] Although unfractionated heparin has been the primary anticoagulant linked to drug-induced alopecia, low-molecular-weight heparins, warfarin, and direct-acting oral anticoagulants have also been implicated as causative agents.[4,10,11,28,171-173] Warfarin typically induces mild, diffuse alopecia with an onset between 3 and 20 weeks after the initiation of therapy. Most cases of hair loss secondary to warfarin or heparinoid drugs go unnoticed by the patient. Only 20% of those who experience hair loss associated with these drugs exhibit clinically evident alopecia. Scalp hair is the primary target, but eyebrows, axillary, and pubic hair also may be affected. Total alopecia is extremely rare.[19,28]

RETINOL/RETINOIDS

Vitamin A, or retinol, is often prescribed for the treatment of hair disorders. However, alopecia of the telogen effluvium type can occur in association with ingestion of vitamin A in doses >50,000 international units daily (whether dietary, such as cod liver oil, or pharmaceutical) over a period of several months.[18] Other retinoids such as acitretin, etretinate, and isotretinoin also cause hair loss.[26] Alopecia associated with these agents usually occurs after 3–8 weeks of therapy. Alopecia may occur after exposure to lower doses, but the onset is longer than 8 weeks. Alopecia is diffuse and involves not only the scalp but also eyelashes, eyebrows, pubic and axillary hair.[19] Lightening of hair color and hair kinking can also occur in association with retinoids.[18]

Table 9-1 Agents Implicated in Drug-Induced Alopecia[18-169]

Drug	Incidence	Level of Evidence[a]
AMPHETAMINES/CNS STIMULANTS		
Amphetamine aspartate[18-20,b]	<1%	C
Benzphetamine[18-20,b]	NK	C
Dextroamphetamine[18-20,b]	NK	C
Dexmethylphenidate[18-20,b]	NK	C
Diethylpropion[18-21,b]	NK	C
Lisdexamfetamine[18-20,b]	NK	C
Methamphetamine[18-20,b]	NK	C
Methylphenidate[18-21,b]	NK	C
ANABOLIC STEROIDS/ANDROGENS		
Fluoxymesterone[6,13,20,22,23]	NK[c]	C
Danazol[6,13,20,22,23]	NK[c]	C
Dihydroepiandrosterone (DHEA)[6,13,20,22,23]	NK[c]	C
Methyltestosterone[6,13,20,22,23]	NK[c]	C
Nandrolone[6,13,20,22,23]	NK[c]	C
Oxandrolone[6,13,20,22,23]	NK[c]	C
Oxymetholone[6,13,20,22,23]	NK[c]	C
Progesterone[6,13,20,22-24]	NK[c]	A
Stanozolol[6,13,20,22,23]	NK[c]	C
Testolactone[6,13,20,22,23,25]	Up to 66%	A
Testosterone[6,13,20,22,23]	NK[c]	C
ANGIOTENSIN-CONVERTING ENZYME INHIBITORS		
Benazepril[26]	<1%	C
Captopril[26]	1–5%	C
Enalopril[26]	NK	C
Lisinopril[26]	NK	C
Quinapril[26]	NK	C
Ramipril[11]	NK	C
ANTIARRHYTHMICS		
Amiodarone[27]	1–4%	C
ANTICOAGULANTS		

Apixaban[28]	NK	C
Dabigatran[28]	NK	C
Dalteparin[28]	NK[d]	C
Enoxaparin[28]	NK[d]	C
Heparin[23,28]	0–50%	C
Nadroparin[16]	NK[d]	C
Rivaroxaban[28]	NK	C
Warfarin[11,28-31]	>5%	C
ANTICONVULSANTS		
Carbamazepine[9,32,33]	0.01–6%	C
Ezogabine[21]	<2%	C
Felbamate[26]	NK	C
Gabapentin[26,34]	0.1–1%	A

CNS = central nervous system, NK = not known; NSAIDs= nonsteroidal anti-inflammatory drugs.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Weight loss may play a role in amphetamine-induced hair loss.

[c] Although the incidence is not known, it is believed to occur commonly.

[d] Although the incidence is not known, it is believed to occur rarely.

[e] Abnormal hair texture has been observed in association with topiramate.

[f] “Perming” effects may be observed in association with valproic acid.[39]

[g] Incidence only reported when antifungal agents were administered for months at high doses.

[h] Combinations of indinavir plus ritonavir may be associated with severe hair loss.[18] Thoracic, axillary, pubic, thigh, and leg hair loss are also frequently adverse effects of indinavir.

[i] Bleomycin, dactinomycin, doxorubicin, and etoposide may cause delayed alopecia.[11,21,52,55-58]

[j] Hair color changes have been reported such as depigmentation[21,49]; incidence of hair color changes associated with cabozantinib was reported as 34%[49]; (incidence of hair discoloration from pazopanib was noted to be 23–39%[21-49]; incidence of hair discoloration from sunitinib was noted to be 20–29%).[109]

[k] Hair loss associated with docetaxel, is sudden in onset (usually during the third week after the first 1-hour infusion) and complete in many patients, including loss of axillary and pubic hair, eyelashes, and eyebrows.[60,61]

[l] Methotrexate causes dose-related alopecia.[8,21,74,92-94]

[m] Paclitaxel has been reported to cause loss of all body hair.[14,99-101]

[n] Degree and incidence of alopecia depends on dose and time of exposure.[136,137]

[o] Changes in hair texture, such as loss of curl or wave, often may occur at high hair lithium concentrations.[150]

[p] All thyroid replacement agents implicated, since hyperthyroidism and hypothyroidism are associated with hair

loss.[11,21,162,163]

IMMUNOSUPPRESSANTS

Medications used for rheumatoid arthritis, notably disease-modifying antirheumatic drugs (DMARDs), have been associated with mild, reversible alopecia.[11,26,138] Gold therapy may cause exfoliative dermatitis leading to alopecia. There is a case report of scarring alopecia following gold therapy.[138] Methotrexate-induced alopecia is thought to be dose-dependent.[74,92] Other DMARDs that may cause alopecia include leflunomide and sulfasalazine. Cyclosporine, tacrolimus, and mycophenolate, which are often used following organ transplantation, have also been associated with hair loss.[18,142]

DOPAMINE AGONISTS

Dopamine agonists implicated in alopecia include bromocriptine, levodopa, pergolide, pramipexole, and ropinirole. Alopecia caused by these agents is considered to be a rare adverse effect.[18,174]

INTERFERONS

No correlation has been established between interferon dose and the onset or severity of hair loss. In some patients, alopecia resolves despite continued treatment.[6] Transient localized alopecia has been noted at the injection site in patients treated with interferon alfa. There are also reports of hair shape and hair color changes associated with interferon use.[18]

THYROID MEDICATIONS

Antithyroid medications, including iodine, propylthiouracil, carbimazole, and methimazole can cause iatrogenic hypothyroidism leading to alopecia. Papadopoulos and Harden reported that carbimazole, an agent similar in structure to methimazole, induced alopecia in a small percentage of patients.[162] However, hair regrowth occurred in all cases after carbimazole therapy was discontinued.[162] This reversible type of hair loss is telogen effluvium and is associated with dry scalp and dry and brittle hair.[4,6] In a few case reports, carbimazole-induced alopecia occurred in euthyroid patients.[163] Sometimes the hair loss terminates despite continuation of therapy with carbimazole and methimazole.[19] Thyroid replacement medications can also cause drug-induced alopecia.[175]

ANTIEPILEPTICS

Several antiepileptic drugs have been associated with alopecia.[19] Of these, valproic acid is associated with the highest incidence of hair loss, reported between 2.6% and 12%. Alopecia occurs within 3 months after initiating therapy and is believed to be of the telogen effluvium type. The hair loss is usually transient and may terminate even if the medication is continued.[19] Valproic acid can also affect hair by causing a "perming" effect or "diffuse curliness of the hair." One report stated that this curliness occurred while taking valproic acid for approximately 1 year. The curliness persisted for approximately 30 months of therapy and subsided within approximately 6 months after discontinuation of the therapy.[39] Carbamazepine may also cause hair loss.[6,9,32,33] Other antiepileptic medications that have been associated with hair loss have all been implicated via case reports. In one case, alopecia developed after 2 months of topiramate therapy in a 15-year-old female. Hair loss resolved after discontinuation of therapy and recurred upon reinitiation of topiramate treatment.[37]

PSYCHOTROPICS

Psychotropic drug-induced alopecia tends to manifest with transient mild to moderate hair loss and is reversible upon discontinuation of therapy.[3] In some cases, improvement has occurred spontaneously despite continuation of lithium therapy. Lithium has been associated with dry and limp hair as well as texture changes. There have been some rare reports of loss of body hair associated with lithium use. This effect reversed upon discontinuation of therapy.[32] Lithium-induced hair loss may be a result of lithium-induced hypothyroidism; resolution of the hypothyroid state may reverse the hair loss.[150] Antidepressant agents such as the tricyclic antidepressants, selective serotonin reuptake inhibitors, new-generation antidepressants and the antianxiety agent buspirone have all been implicated in causing alopecia, although this occurs rarely.[32] Atypical and typical antipsychotic agents have also been reported to induce hair loss, which usually occurs several months after the initiation of therapy and is characterized as nonscarring, diffuse alopecia with generalized or localized hair loss commonly affecting the scalp. The alopecia is reversible, usually within 2–5 months after discontinuation of therapy.[176]

HORMONES/ANDROGENS

Two types of oral contraceptive-induced hair loss have been identified. In the first type, hair loss occurs about 3 months after discontinuation of therapy with oral contraceptives. This type of alopecia is similar to postpartum hair loss, in which increased telogen loss is a consequence of the higher percentage of anagen hair maintained during pregnancy. Although hair shedding can appear dramatic, it usually is not noticeable.[6,173]

The androgenic effects of progestin are responsible for the second type of oral contraceptive-induced alopecia. In these cases, modifying therapy to an oral contraceptive with a lower dose of progestin often results in resolution of the alopecia. The incidence of this type of drug-induced alopecia is decreasing because of the lower progestin content of new formulations of oral contraceptives.[18,173,177,178]

Any medication containing androgens or anabolic steroids can produce or aggravate alopecia in women.[11,26,179] For instance, androgenetic alopecia occurs in a small percentage of women receiving hormone-replacement therapy.[18] Methyltestosterone and progestin derivatives such as medroxyprogesterone and norethindrone may, in rare instances, aggravate scalp alopecia. Estrogen also has been associated with increased hair shedding.[177] A review of hormone-replacement therapy with esterified estrogen 0.65–1.25 mg and methyltestosterone 1.25–2.5 mg in 2,556 patients over 13 years verified the occurrence of drug-induced alopecia associated with both hormone replacement combinations.[131] Anabolic steroids such as testosterone and nandrolone may also cause androgen-induced hair loss.[26,163] Antiestrogens and aromatase inhibitors such as tamoxifen and letrozole and gonadotropin-releasing hormone agonists may also be associated with androgenetic alopecia.[18]

TUMOR NECROSIS FACTOR–BLOCKING AGENTS

Several case studies have implicated anti-TNFα agents (also known as biologic agents) with alopecia. This only occurs in certain individuals who are genetically susceptible. This drug-induced alopecia may present months to years after starting a biologic agent.[164,167]

CANCER CHEMOTHERAPY

Cancer chemotherapy-induced alopecia occurs commonly.[6,11,55,175] The agents that are most commonly implicated include bleomycin, cisplatin, cyclophosphamide, daunorubicin, doxorubicin, fluorouracil, methotrexate, and vincristine.[6,11,55,175] **Figure 9-2** depicts a patient with alopecia induced by fluorouracil.[19] Although chemotherapy-induced alopecia is classified as anagen effluvium, it may present with different clinical patterns and be caused by different mechanisms. Evidence shows that the hair follicle may react to the same insult capable of stopping mitosis with shedding patterns consistent with both anagen effluvium and telogen effluvium. When mitotic activity of the hair cycle is arrested, several factors influence hair shedding. Consequently, hair may fall out very quickly or gradually. The onset of anagen effluvium hair loss is typically days to weeks; however, because chemotherapy can induce telogen effluvium, hair loss can start within months. Although hair loss begins in days to weeks, it might not be prominent until 1–2 months.[18,180,181] The onset and degree of hair loss is highly variable depending on the specific medication, dose, pharmacokinetic variables such as half-life and duration of therapy. Combination therapy increases the risk and severity of alopecia.[182] Hair may appear patchy or patterned and typically falls out spontaneously or with brushing or combing.[4,129,138] Chemotherapy-induced alopecia may also involve the beard, eye brows, eye lashes, axillary, and pubic hairs if the chemotherapy is given at high doses for a sufficiently long period of time and with repeated exposures.[180] The majority of male patients with cancer chemotherapy-induced alopecia report that the frequency of shaving is reduced to one to three times a week.[129]

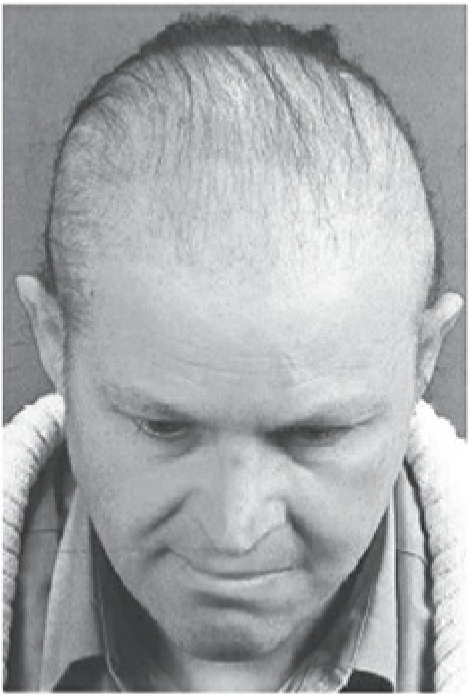

FIGURE 9-2 Diffuse Alopecia Caused by 5-Fluorouracil[19]

Source: Reprinted with permission from Bork K, ed. *Cutaneous side effects of drugs*. Philadelphia: Saunders; Copyright ©1988:249-58.

Scarring alopecia has been noted in association with gefitinib and erlotinib, two tyrosine kinase inhibitors used for treatment of tumors that test positive for the human epidermal growth factor receptor (HER). This alopecia shows chronic folliculitis and perifolliculitis with lymphocytes, plasma cells, and some neutrophils and eosinophils; the upper follicle revealed perifollicular fibrosis, all of which are suggestive of drug-induced scarring alopecia. In the case of the erlotinib, improvement in the scalp occurred after discontinuing erlotinib therapy for 3 weeks. Reintroduction of erlotinib therapy caused a recurrence of the scalp lesions.[72,79] Treatment with lapatinib and trastuzumab, two other agents used for HER-positive tumors, has been reported to cause tufted hair folliculitis, a type of scarring alopecia.[89,123,164,167,183]

Permanent alopecia may occur after conditioning regimens used commonly in hematopoietic stem-cell transplantation and in association with certain cancer chemotherapy agents administered in high doses (e.g., carboplatin).[53,184,185] Combination antineoplastic therapy can also lead to permanent alopecia. Examples include cyclophosphamide, thiotepa, and carboplatin combination therapy, as well as cyclophosphamide administered with busulfan.[184,185]

POISONING AND NONMETAL ELEMENTS

Poisoning with arsenic, bismuth, copper, lead, mercury, or thallium can result in pronounced hair loss, which occurs relatively quickly after exposure.[4,6,136] Hair loss associated with thallium, gold, arsenic, and bismuth usually begins 2–4 weeks after exposure.[13,137] Thallium can affect not only the scalp but also the eyelashes, eyebrows (lateral aspects), arms, and legs. Total epilation may occur approximately 1 month after the initiation of therapy.[4,6] Severe hair shedding usually occurs only in association with the cytotoxic agents. Noncytotoxic drug-induced hair loss rarely results in total hair loss, and is normally reversible upon discontinuation of the offending drug.[18]

ANTIFUNGAL AGENTS

Prior to 2012, antifungals had not been widely associated with alopecia; however, in September 2012, a multistate outbreak of mold-induced meningitis required the use of high-dose and long-term therapy with antifungal agents. Voriconazole was one of the two antifungal drugs used in this outbreak. After several months of therapy, many patients complained of alopecia as well as nail changes including brittle nails, split nails, thinning nails and, in some cases, complete loss of nails. Prior to this, the only antifungal agents that had been associated with alopecia were fluconazole and voriconazole from one case report in one child.[43] In a cross-sectional survey of patients taking a high dose of voriconazole (6 mg/kg every 12 hours) for at least 1 month, 82% reported alopecia. Hair loss occurred on the scalp in 96% of cases, eyebrows and eye lashes in 38%, and arms and legs in 42%. Extensive hair loss requiring a wig or hat was reported in 15% of patients. After discontinuing therapy with voriconazole, 82% of those with alopecia reported that the hair loss had stopped, and 69% indicated that hair regrowth had begun.[43]

EPIDEMIOLOGY

Drug-induced alopecia is not uncommon, although the exact incidence is not known. The incidence of alopecia associated with specific drugs, where known, is presented in Table 9-1.[18-169] Alopecia associated with cancer chemotherapy and cytotoxic drugs, whether noticed or unnoticed, occurs in nearly 100% of patients who do not undergo hair loss prophylaxis. The prevalence and severity depend on the drug as well as on individual predisposition. Hair loss can occur in association with some drugs when administered in usual doses, while alopecia associated with other drugs is unpredictable and occurs only occasionally.[6,11,18,55] Heparin and heparinoid drugs can lead to telogen effluvium, with an incidence that varies from 0% to >50%.[170] Vitamin A (retinol)-induced alopecia has been reported in approximately 20–30% of patients.[6,19] The incidence of DMARD-induced alopecia ranges from 1% to 10%.[13,138-141,170] Alopecia caused by dopamine agonists occurs rarely and is more common in females.[18,174] Nearly 20–30% of patients receiving interferon experience alopecia of the telogen effluvium type.[6] The incidence of alopecia induced by carbimazole ranges from 3.5% to 10%.[162] The overall incidence of hair loss provoked by antiepileptic medications is 0.01–12%, with valproic acid therapy associated with the highest incidence (2.6–12%).[19,37,41] Alopecia induced by carbamazepine has been reported to be a very rare adverse event in some case reports, while others estimate the incidence to be as high as 6%.[6,9,32,33] The incidence of lithium-induced hair loss is 12–17%.[3] Hormone-replacement therapy with esterified estrogen 0.625–1.25 mg and methyltestosterone 1.25–2.5 mg induces alopecia with a reported incidence of 8.8%.[131] Cytostatic agents have been reported to cause total scalp hair loss in roughly 10% of patients. Hair loss was reversed after therapy was discontinued.[4,19,129,186]

MECHANISMS

Mechanisms of drug-induced alopecia are listed in **Table 9-2**.[5,6,43,72,79,166,176,180,187,188] Drugs that induce alopecia can be classified according to their effects on the phases of the hair growth cycle.[1,67] There are two patterns of drug-induced alopecia: anagen effluvium and telogen effluvium.[5,186]

During anagen effluvium, drugs may partially or completely suppress mitosis and cause metabolic impairment of hair growth. This leads to failure to form a hair shaft or the formation of a thinned, weakened hair shaft.[5,186] Eighty-five percent of hair follicles on the scalp are in the anagen phase. Therefore, this is a major target for drugs that cause anagen effluvium alopecia. Hair loss also can be manifested in axillary, pubic, and other body regions. Cytotoxic agents such as cancer chemotherapy drugs and toxic plasma concentrations of certain metals cause drug-induced alopecia by affecting follicles during the anagen phase of hair growth. Because the duration of the anagen phase is the primary determinant of hair length, the maximum length of the new anagen hair is shorter than that of the hair it is replacing. Eventually, the anagen phase is shortened to the point at which the hair cannot reach the skin surface. At this point, the only visible part of the hair cycle on the skin is the pore, as the hair follicle can no longer be seen.[8] In patients with anagen alopecia, hair loss is almost always reversible when therapy with the offending agent is terminated. However, hair grows at a rate of only about 1 cm per month, so several months are required for complete reversal of the hair loss.[6] The medications most commonly associated with anagen effluvium are cancer chemotherapy agents.[5]

The majority of drug-induced hair loss is primarily considered telogen effluvium hair loss, because the majority of drugs that induce hair loss disrupt the telogen effluvium growth phase. In telogen effluvium, drugs provoke hair loss by causing premature termination of the anagen, or growing, phase of the hair cycle, resulting in an increased number of shed hairs. This type of hair loss often can be identified by the presence of a clubbed root on shed hair. Hair loss is typically diffuse rather than patchy, and patients often are asymptomatic. Telogen effluvium is primarily noted on the scalp; however, it sometimes may be detected in other locations.[1,5,6,9] Telogen hair loss often occurs secondary to events such as severe illness, nutritional deficiencies (protein, vitamins, and minerals), childbirth, fever, and hemorrhage. It can be caused by drugs including warfarin, heparin, low-molecular-weight heparins, lithium, certain β-blockers (metoprolol, nadolol, propranolol), and α- and λ-interferon. A few cytotoxic agents also may cause telogen effluvium by shifting the hair follicles into a premature resting cycle.[187,189]

Alopecia areata has been postulated to have an autoimmune pathogenesis involving inflammatory cytokines, including TNFα. Drugs have typically not been associated with alopecia areata, but there are several case reports of biologic agents inducing this type of hair loss.[166,167,190] It has been proposed that anti-TNFα agents lead to the development of other autoimmune diseases, in which the body's immune system is inappropriately activated by the anti-TNFα agents, which then attacks hair follicles.[166,167,191,192] The mechanism is unknown but a proposed hypothesis is that the alopecia is caused when an alternative signaling pathway leads other autoimmune diseases to develop such as psoriatic alopecia or alopecia areata.[164,167]

Table 9-2 Mechanisms of Drug-Induced Alopecia[5,6,43,72,79,166,176,180,187,188]

Drug	Mechanism

Amphetamines	Telogen effluvium
Anabolic steroids/androgens	Androgenetic alopecia
Anesthetics	Telogen effluvium
Angiotensin-converting enzyme inhibitors	Telogen effluvium
Antiarrhythmics	Telogen effluvium
Anticoagulants	Telogen effluvium
Anticonvulsants	Telogen effluvium
Antifungals	Telogen effluvium
Antivirals	Telogen effluvium
β-blockers	Telogen effluvium
Calcium-channel blockers	Telogen effluvium
Cancer chemotherapy agents	Anagen effluvium
Erlotinib	Plus scarring alopecia
Gefitinib	Plus scarring alopecia
Lapatinib	Plus scarring alopecia
Trastuzumab	Plus scarring alopecia
Cholesterol-lowering agents	Telogen effluvium
Colony-stimulating factor	Telogen effluvium
Contraceptives (oral/intrauterine)	Androgenetic alopecia
Corticosteroids	Telogen effluvium
Dopamine agonists	Telogen effluvium
Gonadotropin-releasing hormone-releasing agonists	Androgenetic alopecia
Gout medications	Telogen effluvium
Histamine$_2$-receptor antagonists	Telogen effluvium
Heavy metals/toxins	Anagen effluvium
Immunosuppressants	Telogen effluvium/alopecia areata
Interferons	Telogen effluvium
Multiple sclerosis agents	Unknown
NSAIDs	Telogen effluvium
Psychiatric medications	Telogen effluvium
Retinoids	Telogen effluvium
Thyroid medications	Telogen effluvium
Tumor necrosis factor–blocking agents	Psoriatic alopecia or alopecia areata
MISCELLANEOUS AGENTS	
Aminoglutethimide	Telogen effluvium
Boceprevir	Telogen effluvium
Cetirizine	Telogen effluvium
Clonidine	Telogen effluvium
Diazoxide	Telogen effluvium

Ethionamide	Telogen effluvium
Exenatide	Telogen effluvium
Gentamicin	Telogen effluvium
Imiquimod	Telogen effluvium
Isoniazid	Telogen effluvium
Nitrofurantoin	Telogen effluvium
Naltrexone	Telogen effluvium
Onabotulinumtoxin A	Telogen effluvium
Pasireotide	Telogen effluvium
Vasopressin	Telogen effluvium

NSAID = nonsteroidal anti-inflammatory drug.

Drugs also may induce hair loss by increasing androgen activity. Hair loss occurring by this mechanism is termed *androgenic alopecia* or *androgenetic alopecia*, also known as male pattern baldness. Women with androgenetic alopecia have lower scalp follicle concentrations of 5α-reductase (which converts testosterone to dihydrotestosterone), lower scalp follicle concentrations of the gene encoding aromase CYP19A1 (which converts testosterone to estrogen), and greater density of androgen receptors. However, these patients do not have higher plasma concentrations of androgens and tend to have normal fertility, menses, and endocrine function.[193-195] Drugs implicated in androgenetic alopecia include danazol, metyrapone, progestins, estrogen receptor antagonists, and anabolic steroids.[5,13,58] In many cases, hair loss is not reversible upon discontinuation of therapy with the offending agent.[5]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms associated with drug-induced alopecia are listed in **Table 9-3**.[1,4-6,12,13,58,175,193,196-198] Features of different types of drug-induced alopecia are compared in **Table 9-4**.[4-6,11-13,18,58,167,173,193,197,198] To determine the type of drug-induced alopecia, patients should be evaluated for the presence of shedding or fragile hair (or both), slowed rate of hair growth, inability to regenerate new hair, and any related local or systemic disorders. In addition to a visual inspection, specific diagnostic procedures such as the hair-pull test, hair plucks, microscopic examination of hair and scalp, as well as cultures and biopsies may be used.[1] The hair-pull test is one of the easiest tests used to evaluate alopecia. Patients are advised not to shampoo the hair for 24 hours prior to the test.[193] The clinician grasps approximately 60 hairs using the thumb and index and middle fingers. The hairs are gently but firmly pulled. The test is considered positive for active shedding when more than six hairs are pulled free.

When a definitive diagnosis is needed or if the routine testing is inconclusive, a scalp biopsy can be performed. The scalp biopsy provides histologic features, the number of anagen and telogen hairs, and the number of terminal and vellus hairs per area, which provides a more definitive analysis of the hair loss. A scalp biopsy leaves a small scar on the patient's scalp, as it is an invasive procedure. Patients may refuse the biopsy because of the scar if the hair loss is potentially irreversible. A scalp biopsy is usually not necessary for routine diagnosis of hair loss.[12] The biopsy is usually reserved for alopecia that lacks identifiable triggers, chronic hair loss, miniaturized hair shafts, or failure to exclude alopecia areata.[200]

Patients with drug-induced anagen alopecia present with hair that is thin and fragile, and shed hairs are narrow, broken, and have no roots.[5] Because the hair is weakened, it is susceptible to fracture with minimal trauma.[5,201] Microscopic examination of hair from patients with cancer chemotherapy-induced alopecia reveals fragmentation, trichorrhexis, decreased diameter, and depigmentation of the hair shaft. The hair breaks off nearly as quickly as it issues from the hair follicle.[187,197] Anagen effluvium alopecia usually develops within days to weeks after the initiation of therapy with the causative agent, and the hair shedding is acute but may not be prominent until 1–2 months.[180] Hair may appear patchy or patterned, and typically falls out spontaneously or with brushing or combing.[4,18,129] Often, the hair loss is very severe, especially when two or more alopecia-provoking drugs are administered.[182] Anagen effluvium alopecia may produce loss of most of the scalp hair, eyelashes, and eyebrows. This type of alopecia occurs almost exclusively in association with cytotoxic drugs such as cancer chemotherapy agents. Normally, hair regrowth occurs rapidly if therapy with the causative agent is discontinued and minimal damage to the hair follicles occurred.[18,19,129,175,180,182]

Table 9-3 Signs and Symptoms Associated with Drug-Induced Alopecia[1,4-6,12,13,58,175,193,196-198]

Anagen effluvium alopecia

- Acute severe hair shedding with an onset of days to weeks after the initiation of therapy
- Hair loss from other sites is less common
- May cause loss of hair from entire scalp, eyebrows, and eyelashes; often >200 hairs are shed daily
- Photograph/visualization of scalp reveals diffuse thinning, which may progress to loss of entire scalp hair
- Positive hair-pull test
- Trichogram/TrichoScan reveals weakening and thinning of hair shaft, hair shaft breaks easily at the base with minimal trauma, and/or dystrophic hair (toxically damaged hair)

Telogen effluvium alopecia

- Hair loss is usually diffuse and mild; many times, it is not noticeable at all
- Hair loss occurs usually within 2–4 months after the initiation of therapy
- Increased hair shedding can vary from day to day (often ~100–150 hairs per day)
- Occasional loss of pubic or body hairs can occur
- Photograph/visualization of scalp reveals diffuse thinning; may progress to entire scalp hair loss
- Positive hair-pull test
- Scalp biopsy shows absence of inflammation with increased telogen count
- Shed hair has clubbed roots
- Trichogram/TrichoScan often reveals that scalp and hair shafts appear normal

Androgenetic alopecia

- Hair loss is nonscarring
- Hair-pull test reveals high telogen count
- Photograph and/or visualization of scalp reveals diffuse thinning, specific areas of hair loss, progression of hair loss in androgenetic pattern
- Scalp biopsy (possible histologic features) reveals fraction of terminal hair is decreased, nonspecific focal perivascular basophilic degeneration of the lower third of the connective-tissue sheaths of otherwise normal anagen follicles, perifollicular lymphocyte infiltrate at the level of the sebaceous duct, and/or fibrotic streamers present
- Trichogram/TrichoScan reveals shorter, finer, and often lighter-colored hair shafts

Female androgenetic alopecia

- Diffuse thinning typically occurs at vertex but can spread to the crown
- For the most part, the frontal hair line is preserved

Male androgenetic alopecia

- Hair loss begins at the frontal hairline and causes a receding hairline and possibly thins the hair at the crown, then can spread
- Hair loss is nonscarring
- Preservation of the follicular ostia is observed

Alopecia areata

- Biopsy reveals peri- and intrafollicular inflammatory infiltrate of the hair follicle (around anagen stage)
- Often hair loss is in patches but can involve total scalp hair loss and rarely total body hair loss
- Positive hair-pull test
- Short hairs that taper near the scalp are found near margin of the alopecia (“exclamation point” hairs)

Table 9-4 Comparison of Features of Drug-Induced Alopecia[4-6,11-13,18,58,167,173,193,197,198]

Feature	Anagen Effluvium	Telogen Effluvium	Androgenetic Alopecia	Alopecia Areata
Onset of hair loss	Days to weeks	Becomes evident within 2–4 months	2–4 months (gradual with progression)	1 month to years
Description of hair loss	Extensive or severe hair loss can occur Sometimes complete hair loss can occur, especially with certain cancer chemotherapy agents	Usually mild and diffuse, often not noticed at all	First appears as telogen effluvium then proceeds to androgenetic alopecia if drug therapy is continued In males, primarily bitemporal recession of the hairline; in women, a diffuse thinning over the scalp with more noticeable thinning in the frontal and parietal areas with preservation of the anterior hairline	Typically starts with a patch of hair loss, then can progress to multiple patches of hair loss In rare events, total scalp hair loss and total body hair loss can occur
Evaluation of the hair follicle	Weakening and thinning of hair shaft; breaks easily at the base with minimal trauma	Scalp and hair shafts often appear normal Shed hair has clubbed roots	Shorter, finer, and often lighter-colored hair shafts often present	Bald areas are usually circular or oval shaped and smooth to touch Short hairs that taper near the scalp are found near margin of the alopecia ("exclamation point" hairs)
Results if therapy with causative drug is discontinued	Usually resolves; however, if long-term exposure to drug, may result in a scarring alopecia (which does not resolve with discontinuation of therapy)	Nearly always resolves with discontinuation of therapy or lower doses of the causative drug	In many cases, it is not reversible upon discontinuing the causative agent	Usually resolves completely with discontinuation of agent in conjunction with treatment In cases of alopecia totalis or alopecia universalis, may see treatment failure or not have complete resolution of the alopecia

Patients with drug-induced telogen alopecia typically present with mild, diffuse hair loss. Shed hair typically has clubbed roots and the hair comes out by the roots. Miniaturized hairs are generally not found.[1,5,6,8,202] Alopecia in patients with telogen effluvium is usually subclinical and rarely involves more than 50% of the hairs.[6,186,202,203] Although presentation depends on the percentage of hair follicles involved, hair loss in patients with drug-induced telogen alopecia often does not become evident until 2–4 months after the initiation of therapy with the offending drug.[197] As the hair loss is mild and often occurs long after therapy with the offending agent has been initiated, this condition can be easily overlooked. Hair loss is generally diffuse rather than patchy, and patients often are asymptomatic. Telogen effluvium is noted primarily on the scalp; however, it sometimes may be detected in other locations.[1,5,6,9] Examination of shed hair reveals the presence of a clubbed root. If on microscopic exam a white bulb is found on the shaft of extracted hair, the test is considered positive for telogen effluvium.[10] Progressive miniaturization of the hair follicles is noted. If the offending drug is continued, with each successive growth cycle, hair follicles become smaller and produce shorter, finer hairs that cover the scalp poorly.[170] In telogen effluvium, the hair root is not damaged so hair will, in most cases, spontaneously regrow once therapy with the offending drug is discontinued.[6,186,203] Severe shedding is uncommon and occurs exclusively in association with interferons, anti-retroviral drugs, heparin and heparinoids, and, on occasion, cancer chemotherapy agents.[18] Hair regrowth normally occurs within 2–6 months after discontinuing therapy with the causative agent.[11,18,26,175]

Drug-induced androgenetic alopecia may be suspected in patients taking an androgenic drug and in whom hair loss is mediated by the presence of androgen dihydrotestosterone in hair and/or plasma, the hair loss is male-pattern type (no effects on nonscalp hair), the shedding is usually not severe, and the hair comes out by the roots.[11,18,26,175,193,196] Miniaturization of hairs with various lengths and diameters is a classic sign of androgenetic alopecia. With successive anagen cycles, the hair follicles become smaller, manifesting as finer, shorter hair; over time, nonpigmented vellus hairs replace pigmented terminal hairs. In women, androgenetic alopecia often manifests as a diffuse thinning but more concentrated thinning over the top of the scalp with preservation of the anterior hairline, or as complete baldness and loss of all hair except the occipital and temporal fringes.[1,5,58,196] Evaluation of plasma testosterone concentrations is of value in these patients; testing for drug-induced alopecia is expected to yield normal or low concentrations in the absence of other features consistent with androgen excess (e.g., hirsutism, acne, or irregular menses).[5,11,179,193,198] Biopsy of the scalp in women with androgenetic alopecia shows increased aromatase activity compared to that in men with androgenetic alopecia.[177]

Alopecia aerata presents often with bald areas that are usually oval or circular, well-defined, and a smooth patch or patches. The affected area can range from just patches on the scalp to total scalp hair loss (alopecia totalis) and in rare cases to total body hair loss (alopecia universalis). Inflammation is present but usually deep in the skin and is revealed via a scalp biopsy. The hair-pull test reveals pencil point and telogen shafts. In some instances, there is mild itching, tingling, tenderness or a burning sensation in the affected area.[191,192,197] Reports of drug-induced alopecia areata reveal hair loss after several months of therapy which usually progresses if the causative agent is not discontinued. After terminating therapy with the offending medication, hair loss with treatment usually returns but very slowly, often months later.[166,167] Trichotillomania, a result of a psychiatric disorder such as obsessive-compulsive disorder, psychosis, anxiety disorder, is another cause of alopecia and involves a compulsion to pull out one’s hair. The hair loss involves patchy hair loss with incomplete thinning and stubble present. Another cause of alopecia is traction alopecia where the hair is pulled back tightly repeatedly or for long periods of time. It usually presents a frontal and/or temporal hair loss.[10] Conditions to consider in the differential diagnosis of drug-induced alopecia are listed in **Table 9-5**.[4,10]

RISK FACTORS

Risk factors for drug-induced alopecia are listed in **Table 9-6**.[11,161,173,175] Route of administration has been shown to influence the risk of alopecia associated with some drugs. Cancer chemotherapy agents administered intravenously may cause complete alopecia within a short time, whereas oral therapy tends to be associated with a lower risk of alopecia, regardless of the total dose administered. Drug combinations, higher doses, and longer duration of drug therapy as well as drug interactions that lead to increased plasma concentrations can contribute to the risk of alopecia.[187] For example, lithium-induced changes in hair texture, such as a loss of a natural wave or curl, are more likely to occur in patients with significantly higher hair lithium concentrations than in those who do not experience hair changes.[150] The risk of anticoagulant-induced hair loss is not related to age but appears to be dose-related and seems to be more frequent in women than men.[6,19] Alopecia caused by dopamine agonists is also more common in women.[18,174] Vitamin A (retinol)-induced alopecia occurs more frequently in women receiving higher doses. Vitamin E, taken concurrently with vitamin A, may potentiate vitamin A toxicity.[6,19] Patients with pre-existing thyroid disease, polycystic ovary disease, inflammatory diseases such as seborrheic dermatitis, psoriasis, malnutrition, or certain metabolic disorders such as liver disorders and chronic kidney disease are at risk for alopecia.[1,204] Concomitant systemic and chronic illness such as autoimmune disorders and cancer may also increase the risk. Stress, crash dieting, nutritional deficiencies (protein, vitamins, and minerals), iron deficiency infection, fever, and childbirth are other factors that can lead to telogen effluvium.[4,10,177,189] Women with androgenetic alopecia who take a progestin with high androgenic activity for oral contraception or hormone-replacement therapy are at increased risk for further hair loss. Testosterone and related substances such as dehydroepiandrosterone (DHEA) should be avoided in women with androgenetic alopecia because of the increased risk for worsening the condition.[196]

Table 9-5 Conditions to Consider in the Differential Diagnosis of Drug-Induced Alopecia[4,10]

Alopecia areata, scarring alopecia, telogen effluvium

Systemic/chronic illness (e.g., autoimmune disorder, cancer)

Alopecia areata, telogen effluvium

Hypothyroidism

Androgenetic alopecia (women)

Hirsutism (combined hirsutism/alopecia in polycystic ovary disease)
Amenorrhea
Infertility

Scarring alopecia, telogen effluvium, tinea capitis

Infection (systemic or local)

Telogen effluvium

Physical stress (e.g., surgery, pregnancy, malnutrition)
Life-threatening psychological stress

Telogen effluvium; anagen effluvium

Serious illness within previous 3–4 months

Traction alopecia

Tight braids
“Pulled-back” hairstyle

Trichotillomania

If taking psychoactive medication, also consider telogen effluvium, as both types of alopecia could be occurring simultaneously
Psychiatric disorder (e.g., psychosis, anxiety, obsessive-compulsive disorder)

Table 9-6 Risk Factors for Drug-Induced Alopecia[11,161,173,175]

Risk factors related to drug administration:

Combination therapy
Drug interactions leading to higher drug concentrations
Higher doses
Intravenous route of administration
Longer duration of exposure

Disease states:

Autoimmune disease
Endocrine abnormalities
Hyperandrogenic disorders
Hypothyroidism or hyperthyroidism
Illness/fevers/infection

Increased blood loss

Inflammatory diseases (i.e., seborrheic dermatitis, psoriasis)

Iron deficiency anemia

Parturition

Polycystic ovary syndrome

Poor nutritional status/crash diets (low serum iron or ferritin concentrations or deficiency of protein, zinc, selenium)

Family history of androgenetic alopecia

Recent surgery

Stress

Postoperative alopecia is the temporary or permanent loss of hair that occurs following prolonged immobilization during general anesthesia and intubation.[199] Localized pressure-induced ischemia is the likely cause. Patients at highest risk for permanent hair loss include those undergoing cardiac or gynecologic surgical procedures for which the combined intraoperative and postoperative intubation time exceeds 24 hours.

MORBIDITY AND MORTALITY

Although drug-induced hair loss is usually reversible, it can be quite traumatic for both men and women.[79] In one study, cancer chemotherapy-induced alopecia ranked third on patients' lists of distressing symptoms, behind nausea and vomiting.[205] Patients sometimes refuse cancer chemotherapy for fear of hair loss.[74] It is important that clinicians appreciate their patients' views regarding the social impact of hair loss, even in cases in which patients experience only hair thinning. Understanding patients' feelings regarding hair loss and openly discussing the matter may reduce the risk that they will abruptly discontinue medications and suffer potentially serious health consequences as a result.[32]

PREVENTION

Avoiding therapy with medications that may cause alopecia is the best method of prevention, but in many cases this is not feasible. In situations in which drug-induced alopecia may occur, continuation of therapy may be necessary, particularly with cancer chemotherapy agents, anticoagulants, or psychiatric medications. In such cases, clinicians should use the lowest possible dose of the potentially causative agents and avoid, when possible, the use of multiple drugs with the potential to cause hair loss. In addition, the duration of exposure should be limited to the extent possible, and the oral, rather than intravenous, route should be used whenever possible.[178,187] Delivery of anthracyclines via liposomes significantly reduces the risk of hair loss compared with other routes of administration.[52] Avoiding drug interactions that lead to increased plasma concentrations of alopecia-inducing drugs is also important, especially if the alopecia is dose-dependent. Approaches to help prevent drug-induced alopecia are presented in **Table 9-7**.[6,10,11,52,177,178,187,206-209]

Table 9-7 Approaches to Help Prevent Drug-Induced Alopecia[6,10,52,177,178,187,206-209]

- Avoid drug interactions that could increase plasma concentrations of potentially causative agents associated with dose-dependent alopecia
- Avoid drugs with potential to induce alopecia where possible
- Avoid, when possible, the use of multiple drugs with the potential to cause hair loss
- Check plasma iron and ferritin concentrations and thyroid function at first sign of hair loss
- For patients undergoing cancer chemotherapy, consider scalp cooling or hypothermia
- Identify and manage comorbid diseases and conditions that can cause or exacerbate hair loss, such as infections, fevers, malnutrition, polycystic ovary syndrome, hyperinsulinemia, inflammatory diseases, and autoimmune diseases
- Identify any family history of androgenetic alopecia, hirsutism, amenorrhea, or infertility prior to initiation of therapy with medications known to cause hair loss; this may allow the clinician to identify and correct potential risk factors for alopecia
- Limit duration of exposure to potentially causative agents
- Maintain proper nutritional status
- Manage stress
- Monitor kidney and/or liver function in patients taking renally eliminated or hepatically metabolized drugs known to cause dose-dependent alopecia
- Recognize patients at high risk for alopecia or existing alopecia to avoid alopecia-inducing medication if possible or consider prophylactic therapy such as minoxidil
- Use liposomal delivery of the anthracyclines to significantly lower risk of hair loss
- Use the lowest possible dose of potentially causative agents
- Use the oral route rather than the intravenous route whenever possible
- Warn patients with breast cancer or lymphoproliferative disorders of the potential for interference with drug delivery if using scalp cooling; scalp cooling should be avoided in patients with hepatic dysfunction

Other preventive measures include ensuring proper nutritional status and management of stress. Stress and anxiety are often present in patients who are taking psychotropic medications and are also symptoms of malnutrition. Stress, anxiety, and malnutrition are each well-documented causes of hair loss. Therefore, patients taking drugs known to cause alopecia may experience hair loss due to the medication, stress, anxiety, or any combination of these factors. Consequently, helping the patient cope and gain better control of his or her disease state may reduce stress and anxiety and may decrease the risk or severity (or both) of hair loss induced by psychotropic medications.[11,26]

Diseases or conditions that can cause or exacerbate hair loss, such as infections, fever, malnutrition, polycystic ovary disease, hyperinsulinemia, inflammatory diseases, and autoimmune disorders should be identified and managed appropriately and ameliorated, if possible. Prior to the initiation of therapy with drugs known to cause alopecia, assessment of plasma iron and ferritin concentrations and thyroid function, identifying any family history of androgenetic alopecia, and detection of conditions associated with androgen excess, such as hirsutism, amenorrhea, or infertility may allow the clinician to identify and correct potential risk factors.[10,11,177] Methotrexate-induced alopecia may be prevented with folic acid supplementation.[74,92] There are a few reports that valproic acid-induced hair loss may be prevented with zinc and selenium supplementation, dose reduction, or both.[32,40,41,210] In general, maintaining patients' euthyroid status will aid in preventing antithyroid-induced alopecia.[210] The risk of postoperative alopecia may be reduced with frequent intraoperative and postoperative head repositioning.[199]

Patients with a family history of androgenetic alopecia are at high risk for androgenetic-induced alopecia associated with certain oral contraceptives. In these patients, selection of an oral contraceptive with little to no androgenic effects, such as norgestimate or ethynodiol diacetate, may reduce the risk of alopecia.[161,196] Prophylactic therapy with topical minoxidil can be prescribed when a patient with a family history of androgenetic alopecia requires long-term therapy with a medication known to induce androgenetic alopecia. Minoxidil is not effective for prevention of cancer chemotherapy-induced alopecia, but it will help reduce the severity and duration of the alopecia.[211,212]

Scalp cooling and hypothermia are of questionable efficacy for the prevention of cancer chemotherapy-induced alopecia, but it can possibly help the degree of chemotherapy-induced alopecia. Scalp cooling involves applying a cooling turban around the scalp with a tourniquet pressure ranging from 30 to 50 mm Hg above systolic blood pressure 10 minutes prior to drug administration, followed by removal 30 minutes after drug administration application. Hypothermia involves cooling the scalp to at least 24°C for 5 minutes before, during, and 20 minutes after the infusion of cancer chemotherapy.[6,52] Some investigators have raised concerns that, in some cases, these methods may be detrimental because of a possible reduction of delivery of chemotherapy drugs to intended areas, or when chemotherapy is being used for generalized hematogenic metastases or there is a high likelihood of metastasis to the scalp, such as in patients with breast cancer or lymphoproliferative disorders.[52,206] Liver dysfunction may also impair the potential efficacy of these preventive measures, as it inhibits the metabolism of some chemotherapy agents, thereby allowing drug concentrations to persist beyond the protective time frame of induced scalp hypothermia.[207,208,209]

A scalp cooling device, DigniCap, has been approved by the U.S. Food and Drug Administration (FDA) in the United States with the indication of decreasing the risk of chemotherapy-induced alopecia among women battling breast cancer. In a trial of more than 100 women with breast cancer, only 34% of those who used the cap lost over half their hair, compared to 100% in the control group. No serious adverse events were noted. The tight-fitting silicone cap has a coolant that circulates throughout the cap with a temperature that never goes below 32°F (0°C). The DigniCap is an important device as some women have opted out of chemotherapy due to the alopecia and with the prevention of hair loss in these patients may be a significant benefit to their quality of life. The FDA concluded from the studies that the risk of a decrease in chemotherapy delivery to an isolated grouping of the breast cancer cells in the scalp via the use of the cold cap is extremely rare.[213]

MANAGEMENT

DRUG THERAPY

Retinoid-induced alopecia is quickly reversible when the dose is decreased or vitamin A supplementation is discontinued. Hair regrowth occurs in approximately 2–3 months.[6,19] Dopamine-induced alopecia is reversible following discontinuation of therapy.[18,133] Chemotherapy-induced alopecia almost always resolves after discontinuation of therapy, and hair regrowth tends to occur rapidly. However, the texture and color of regrown hair may be different.[18] In rare cases associated with exposure to cancer chemotherapy over a long period, atrophy of the hair bulb may occur. However, most believe that this atrophy is always reversible after discontinuation of therapy with the causative agent.[19,129] In the case of lapatinib-induced alopecia, after a dose reduction, there was improvement.[89,123]

For patients with drug-induced telogen alopecia, hair growth returns when the causative agent is discontinued or the dose is decreased. Usually, additional treatment is not necessary.[18,186,202,209] When discontinuation of therapy or dose adjustment is not possible, a trial with topical minoxidil is recommended (**Table 9-8**).[1,6,8,10,11,13,52,173,193,203,206-209,211,213-221]

Table 9-8 Treatment Options for Drug-Induced Alopecia[1,6,8,10,11,13,52,173,193,203,206-209,211,213,215-221]

Treatment	Dose and Administration	Comments
TOPICAL TREATMENT		
Minoxidil	2% solution (men and women), apply twice daily 5% solution (men only), apply twice daily 5% foam (men only), apply twice daily	Solution: A dropper or extended-spray applicator must be used to apply the solution directly to the scalp Foam: Place a capful in hand and apply foam directly to the scalp; monitor for hypertrichosis and skin irritation; wait 4 hours before washing or swimming; after applying, do not allow scalp to become wet from the rain; should not be used in pregnant or nursing women
Anthralin cream (alopecia areata only)	0.1%, 0.25%, 0.5%, and 1% creams Apply once daily; start with 5-minute duration of therapy at a time and work up to as long as 1 hour After each application period, the scalp should be rinsed thoroughly with cool-to-lukewarm water and then cleansed with shampoo	New hair growth becomes apparent in 2–3 months Adverse effects include erythema, pruritus, scaling folliculitis, pyoderma, and regional lymphadenopathy Withholding treatment for a few days results in rapid resolution of adverse effects; treatment then can be restarted, but anthralin should be left on for shorter periods Staining of clothes and skin can occur
Topical steroids (alopecia areata only)	Twice daily application of an intermediate-potency corticosteroid solution or lotion to the entire scalp Commonly used agents: Fluocinolone acetonide cream 0.2% and betamethasone dipropionate cream 0.05%	Typically not as effective as intradermal steroid treatment Primarily used in combination therapy and not monotherapy Commonly used with corticosteroid injections, anthralin, or minoxidil Treatment duration is a minimum of 3 months before hair regrowth can be expected; maintenance therapy is often necessary
INTRALESIONAL INJECTIONS		
Corticosteroids: triamcinolone acetonide (alopecia areata only)	Strength range: 2.5–10 mg/mL, but the 5-mg/mL concentration is the most often used; inject intralesionally in multiple sites 1 cm	Hair grown usually apparent in 4 weeks Treatment every 4–6 weeks as

	apart; inject 0.1 mL into each site; a maximum volume of 3 mL on the scalp in one visit is recommended Use 0.5-inch long, 30-gauge needle	needed Adverse effects: local skin atrophy and telangiectasia, which can be minimized by specifically injecting into mid-dermis rather than into the more superficial epidermis or the subdermal fat Topical anesthetic may be applied 30–60 minutes before the treatment to alleviate injection pain
ORAL TREATMENT		
5α-reductase inhibitors	Finasteride: 1 mg orally once daily (male and female) Dutasteride: 0.5 mg orally once daily (male and female)	Benefits not evident for 4 months or longer May be combined with minoxidil For women: rule out pregnancy before use; if child-bearing age, use contraception
Corticosteroids: prednisone (alopecia areata only)	For extensive or rapidly spreading alopecia areata in adults >60 kg: 40 mg prednisone daily × 7 days; then taper slowly by 5 mg every few days × 6 weeks For less extensive alopecia areata: 20 mg prednisone daily or every other day followed by slow tapering in increments of 1 mg when hair loss is stable	Seldom used due to adverse effects Reserved for use with progressive alopecia areata Used in combination with topical or injected corticosteroid therapy as well as with topical minoxidil therapy
Cyproterone (for use in women only; not available in the United States)	50 mg orally daily OR 50–100 mg for 10 days/month if premenopausal	Rule out pregnancy before use; use contraception, if applicable May be used with minoxidil Monitor for dyslipidemias, weight gain, depression
Flutamide (for use in women only)	250–500 mg orally daily (doses of 250–375 mg may be less hepatotoxic)	Reserved for refractory disease due to potential for hepatotoxicity
Oral contraceptives (for use in women only)	Ethinyl estradiol + drospirenone Ethinyl estradiol + norgestimate Ethinyl estradiol + ethynodiol diacetate 1 tablet orally at bedtime (low-androgenic-activity progestin)	Efficacy studies are lacking Often combined with spironolactone
Spironolactone (for use in women only)	100–300 mg orally daily (often need ≥200 mg/day)	Rule out pregnancy before use; use contraception, if applicable

		May be used with minoxidil Monitor serum potassium concentrations, blood pressure, dizziness
PRIOR TO CANCER CHEMOTHERAPY		
Scalp cooling	Involves applying a cooling turban around the scalp with tourniquet pressure ranging from 30 to 50 mm Hg above systolic blood pressure 10 minutes prior to drug administration and then removed 30 minutes after drug administration	These methods may be detrimental because of a possible reduction of distribution of chemotherapy to intended areas or when chemotherapy is being used for generalized hematogenic metastases or if there is a high likelihood of metastasis to the scalp such as in breast cancer or lymphoproliferative disorders
DigniCap (approved only for females with breast cancer)	The silicone cooling cap is fitted onto the head 30 minutes prior to chemotherapy; the cap is worn throughout the chemotherapy infusion and continued after therapy depending on the chemotherapy drug and dose; this postinfusion cooling time usually lasts 30–150 minutes; once postinfusion cooling is complete, the cap will be kept on the head for 15 minutes as the cap warms up to diminish any discomfort	FDA concluded minimal risk of reduced chemotherapy to intended areas when treating breast cancer The most common adverse effects of the cooling system include cold-induced headaches, chills, neck and shoulder discomfort, and pain associated with wearing the cooling cap for the required period of time DigniCap is not recommended for use in patients with hematological malignancies
Hypothermia therapy	Cool the scalp to at least 24°C for 5 minutes before, during, and 20 minutes after the infusion of chemotherapy	
AFTER CHEMOTHERAPY, IF SCARRING OCCURS		
	Topical steroids (Clobetasol topical solution) Acitretin 25 mg orally once daily Isotretinoin 15 mg orally twice daily	Skin dryness; erythema
COSMETIC OPTIONS		
Hairpiece, wig, hairstyling		Often used by patients faced with temporary or permanent alopecia
SURGICAL OPTIONS		
Hair transplantation	Cylindrical grafts Elliptical grafts	Can be expensive For more extensive balding, more than one method is necessary

	Minigrafts and micrografts	
Scalp reduction Transposition flap Soft-tissue expansion		
MISCELLANEOUS OPTION		
Low-level laser therapy (LLLT)	655 nm wavelength Focus light for several minutes to each infected area	Relatively inexpensive No adverse effects; can be combined with other methods

FDA = U.S. Food and Drug Administration.

Use of minoxidil for the prevention and treatment of chemotherapy-induced alopecia does not prevent the onset of hair loss but has shortened the duration or reduced the severity of the hair loss.[212,222] In one study, minoxidil shortened the period of hair loss to regrowth from 137 to 50 days.[222]

Minoxidil can be used for the management of any type of drug-induced hair loss. The American Academy of Dermatology guidelines recommend minoxidil as first-line treatment for androgenetic alopecia in men or women.[223] Minoxidil is the only topical agent with proven efficacy for androgenetic alopecia and is the only drug that is FDA-approved for hair loss for both men and women. The drug works by affecting the hair cycle, causing premature termination of the telogen phase, and may also prolong the anagen phase.[215] A 2% strength is available for both men and women and a 5% strength is approved only for men.[11,12] For women who do not respond to the 2% strength, the 5% strength can be used, as it has been shown to provide greater patient satisfaction in one study.[11] However, the incidence of hypertrichosis and scalp contact dermatitis were higher in association with the 5% strength as compared with the 2% strength.[11] Minoxidil solution or minoxidil foam should be applied twice daily to a dry scalp. If the solution is used, a dropper or extended-spray applicator must be used to apply the solution directly to the scalp.[173,196] A capful of the foam product should be applied directly to the scalp with the hands. Patients should be told that at least 4–6 months of treatment is necessary before the effects of minoxidil become evident, and maximum effects may not occur for approximately 1 year.[12,173] Adverse effects of tachycardia and hypotension are very rare (0.001%).[12]

Minoxidil treatment may be required indefinitely, unless therapy with the alopecia-inducing drug is discontinued. However, if minoxidil treatment is discontinued, some if not all of the regained hairs are shed within 3 months.[12,202] Minoxidil has been reported to cause scalp irritation, although the incidence is lower in association with the new foam product. In addition, the foam product contains much less propylene glycol, which is thought to be the cause of the contact dermatitis.[163]

Oral medications are also available for androgen-induced alopecia. However, these drugs have not been studied for the management of drug-induced alopecia. Finasteride and dutasteride exert their effects by inhibiting 5α-reductase type 2, which results in a decrease in plasma dihydrotesterone (DHT) concentrations. Finasteride reduces plasma prostate-specific antigen (PSA) concentrations and, thereby, could impair early detection of prostate cancer. Monitoring PSA concentrations prior to treatment and annually is recommended taking into account its effect when interpreting the results.[221] Finasteride has been on the market for years and has been widely used for the management of androgenetic alopecia in men, whereas dutasteride is relatively new for the treatment of androgenetic alopecia. Dutasteride 2.5 mg daily was found to be superior to finasteride 5 mg daily in increasing scalp hair growth in men.[221] The difference may be that finasteride inhibits only one isoenzyme of 5α-reductase, resulting in a 70% reduction of serum DHT concentrations, while dutasteride inhibits both type 1 and type 2 isoenzymes, reducing serum DHT concentrations by 94–95%.[224] Adverse sexual effects of finasteride and dutasteride such as erectile dysfunction, low libido, and infertility are uncommon and resolve spontaneously in most patients even without discontinuing therapy.[225]

Despite initial failures of finasteride for treatment of women with androgenetic alopecia, more recent data have demonstrated clinical efficacy. One case found that dutasteride 0.5 mg orally once daily provided clinical improvement, accompanied by an increase in mean hair diameter, reduction in variability of hair diameter, and normalization of trichogram results in a 46-year-old female.[224] Both finasteride and dutasteride are well tolerated by women.[224] Dutasteride may have the potential for efficacy in the management of androgenetic alopecia in women as well as men if large, long-term studies demonstrate efficacy.

Recently, topical formulations of finasteride and dutasteride (with and without topical minoxidil) have been used in men and women. Initial reports are promising; however, the necessary research to ensure efficacy and safety is lacking.[221]

For women, other oral antiandrogens that can be used to treat androgen-induced alopecia include spironolactone, cyproterone acetate (which is not available in the United States), and flutamide. However, flutamide is associated with hepatic toxicity and is rarely used.[10,11] Spironolactone, an aldosterone antagonist with antiandrogenic effects, is commonly used in women with androgenetic alopecia at doses of 100–300 mg daily.[13] In patients taking spironolactone, periodic serum potassium concentrations should be determined, as the drug can cause hyperkalemia. In an unblinded trial of 80 women taking spironolactone 200 mg daily or cyproterone acetate 50 mg daily (or 100 mg for 10 days/month in women who were premenopausal), 85% of women in both groups experienced no worsening of female pattern hair loss. If oral antiandrogens such as finasteride or spironolactone are prescribed to females of reproductive age, pregnancy should be excluded prior to use and oral contraceptive therapy or other methods of contraception should be prescribed concomitantly, as these agents are known teratogens.[11,13] Oral antiandrogens have been used alone or in combination with topical minoxidil in men and women.[10,12,226] Some trials in men have shown superior efficacy when minoxidil is combined with finasteride.[12]

Newer oral contraceptives with antiandrogenic effects such as ethinyl estradiol in combination with drospirenone, norgestimate, or ethynodiol are potential treatments for female alopecia.[227] Some premenopausal women taking antiandrogens are using these newer low-dose progesterone oral contraceptives to prevent pregnancy (because antiandrogens are teratogenic) while benefiting from their antiandrogenic effects. Unfortunately, topical and oral antiandrogens such as progestins and estrogens for the treatment of alopecia have not been studied in large trials, and the safety and efficacy of these agents are unknown. These drugs are not used in men because of the potential for sexual adverse effects.[26,161]

There are no supportive data for using oral estrogens, spironolactone, cyproterone acetate, or flutamide to treat or prevent drug-induced androgenetic alopecia in males; however, a case report involving a male-to-female transsexual person with severe male androgenetic alopecia reported flutamide to be effective in partial reversal of hair loss.[221]

The treatment of alopecia areata centers on anti-inflammatory and immunosuppressive therapy. These treatments commonly include corticosteroid injections, corticosteroid topical products, minoxidil, and anthralin. The choice of one agent over another depends on the extent of condition (localized versus extensive), and the patient's personal preference. If more than 50% of the scalp is involved, topical minoxidil plus either anthralin or topical steroid is typically used. Oral corticosteroids are also used at higher dose for 7 days followed by a taper over at least 6 weeks. Unfortunately, patients with alopecia totalis or alopecia universalis usually respond less well to treatment, and therapeutic failure occurs in most of these patients with any mode of management. If the hair loss involves less than 50% of the scalp, intralesional corticosteroid injections are usually prescribed first. Topical minoxidil, topical corticosteroid or oral prednisone can also be administered with the intralesional corticosteroid treatment or as monotherapy.[193,218,228]

Other less popular therapies with mixed reviews include psoralen and ultraviolet A phototherapy, topical immunotherapy, topical retinoids, bexarotene, sulfasalazine, methotrexate, and cyclosporine.[193,218,228] Psoralen and ultraviolet A phototherapy involve controlled exposure of the affected skin to ultraviolet light. The rate of response to this therapy is highly unpredictable (ranging from 15% to more than 70%). If treatment is successful, there is a relapse rate of 26%. Diphenylcyclopropenone is the drug of choice for topical immunotherapy, but it is associated with adverse effects of including cervical lymphadenopathy, a severe eczematous reaction, urticaria, and postinflammatory pigment changes. Topical retinoids such as topical tretinoin lack data from large, double-blind, placebo-controlled studies. In one study of topical retinoids, efficacy was only 55% compared to 70% with topical steroids. In a study of bexarotene gel, only 26% of patients experienced hair regrowth in at least 50% of treated sites. Sulfasalazine, methotrexate, and cyclosporine are all oral immunomodulatory and immunosuppressive drugs with potentially harmful adverse effects and require blood monitoring for white cell counts, serum creatinine and blood urea nitrogen, hematologic toxicity (methotrexate and sulfasalazine), hepatotoxicity (methotrexate and cyclosporine), and serum drug, lipid, potassium, and magnesium concentrations (cyclosporine).[218,228]

An experimental treatment option for various types of alopecia is platelet-rich plasma (PRP), which involves subcutaneous cap injections of autologous plasma with >1,000,000 platelets. PRP contains high concentrations of growth factors to potentially stimulate hair regrowth. PRP can be used in combination with other treatments, is inexpensive, and lacks significant adverse effects; however, thus far, its efficacy remains controversial.[221,229,230]

NONDRUG THERAPY

Cosmetic treatments are also available for addressing all types of drug-induced alopecia and are applicable to both men and women. Common cosmetic treatment options for temporary or permanent drug-induced alopecia include wigs, hair pieces, hair extensions, and hair weaves. There are also dyes available that can be sprayed or applied to the scalp that aid in camouflaging balding areas. Special hairstyling techniques also can be of benefit. These cosmetic measures often can produce satisfactory results.[10]

Surgical procedures are rarely needed for patients with drug-induced alopecia, but they are an option for patients with alopecia that is either permanent or severe or in situations in which therapy with the offending drug cannot be discontinued.[12,173] Hair transplantation or surgical hair restoration is popular with males with androgenetic alopecia. Robotic systems for harvesting hair follicles have been introduced that have improved this procedure. However, the efficacy of these systems has been disappointing for both sexes, due to a wide variation in results associated with different patient characteristics, surgical techniques, and skill levels of surgeons and teams. Another limitation is that these systems cannot arrest the progression of alopecia, which is a problem if the offending drug is continued.[191,221] Other surgical interventions include scalp reduction, transposition flap, and soft-tissue expansion procedures. Table 9-8 provides a list of the various treatment options for drug-induced alopecia.[1,6,8,10,11,13,52,173,193,203,206-209,211,213,215-221]

Low-level laser therapy is one of the newest nondrug treatments for alopecia. It has been studied for therapy of androgenetic alopecia but can be applied to alopecia areata and cancer chemotherapy-induced alopecia. Low-level laser therapy involves the use of low levels of red or near-infrared light, known as photobiomodulation or low-level laser therapy (LLLT), which is believed to work by inducing proliferative activity in the hair follicles resulting in terminalization of vellus hair follicles. There is some debate as to the optimal wavelength, but 655 nm is the wavelength used in clinical studies. LLLT is easy to use and resembles a hairbrush that one places on the head for a few minutes in the affected area while it emits the light therapy. LLLT is relatively inexpensive, can be used in both men and women, is associated with no known adverse effects, and can be easily obtained without a prescription. LLLT can be used both as monotherapy and in combination therapy, such as with topical minoxidil.[191,231]

INFORMATION FOR PATIENTS

Patients experiencing hair loss, whether permanent or temporary, should be informed that it is safe for them to style, blow dry, and tease the hair and use hair spray, hair color, and permanents. This helps patients deal with the cosmetic effects of alopecia.[193,196] Patients with alopecia often decrease the frequency of shampooing because they associate it with increased hair shedding. Patients should be educated regarding the hair growth cycle and should understand the cumulative nature of hair loss. With once-weekly shampooing, patients may experience 7 days' cumulative hair loss at one time, while daily shampooing allows a more realistic assessment of the actual daily hair loss and improves scalp health.[173,177]

If significant alopecia occurs, head coverings, wigs, and hairpieces should be encouraged, and patients should be assured that these cosmetic devices will not interfere with hair regrowth. Use of these cosmetic aids may improve patients' morale.[5] Patients also may benefit from use of a wide-toothed comb or soft-bristled brush and should be instructed to comb hair gently and to avoid excessive brushing, especially if undergoing cancer chemotherapy. Baby shampoo or a protein-enriched shampoo may be optimal in patients with alopecia, and use of a satin pillowcase will minimize friction. If alopecia is excessive, short hairstyles tend to disguise hair thinning, but enough length should be left to possibly allow for arrangement of hair to cover areas of baldness. If hair loss becomes pronounced, some patients prefer to shave the head, which may promote regrowth once the treatment is stopped. If a wig is worn, care should be taken to ensure that the lining is comfortable and not irritating. Applying baby oil, mineral oil, or ointment containing petrolatum and lanolin with some mineral oil and cod liver oil (which contain vitamins A and D) and massaging the scalp may reduce itching and keep the skin soft. Avoiding sun exposure helps protect the scalp.[74]

Patients should be educated regarding the risk of alopecia when a potentially causative agent is prescribed. Although patients find hair loss to be disturbing, alopecia is often tolerable, provided that wigs are available and advance warning regarding hair loss is provided.[74] Patients should also be informed that hair regrowth following chemotherapy may involve new hair that is coarse and has a color change. Hair also may be thinner than it was prior to therapy.[74,187] Patients should be counseled regarding proper nutrition, such as dietary protein intake, and should avoid fad or crash dieting while receiving medications with the potential to induce alopecia.[177]

Patients using topical minoxidil should be warned of its primary adverse effect, which is hypertrichosis or excessive hair growth. Hypertrichosis primarily occurs above the eyebrows, in the malar region, and on the lateral cheek area. Occasionally, hair growth is also noted above the lip and on the chin.[193] Some rare hair growth on the limbs has been noted in association with the 5% solution. Local adverse effects from irritation and contact dermatitis also have been reported with continued use.[202] Switching to the foam product may help minimize the risk of these adverse effects. Patients should be told that an increase in scalp hair shedding may occur during the first months of therapy as the follicles cycle from the telogen to the anagen phase. Patients should be informed that 4–6 months may be required before the effects of minoxidil become evident, and up to 1 year may be required for maximum effects.[12] Patients should be warned that if minoxidil treatment is discontinued and the alopecia-inducing agent is still present, hair loss will resume.[12,13,175] After each use of the topical solution, the hands should be washed to avoid applying solution on other parts of the body. Topical minoxidil should remain on the scalp for at least 4 hours before showering or shampooing.[12] When appropriate, it is important to assure patients that once the drug causing alopecia is discontinued, the alopecia tends to resolve.

Patients taking 5α-reductase inhibitor therapy may experience decreased libido or impotence rarely during therapy that resolves spontaneously in most patients even without discontinuing therapy.[225] To prevent pregnancy in a partner of child-bearing age, men should use barrier contraceptives (even though the risk is negligible) and women of childbearing age should be told to use contraception, because these medications can lead to fetal abnormalities.[12,13,221] Women who are prescribed antiandrogenetic medications should be warned, if applicable, not to become pregnant as these medications are teratogenic.[11] Effects on libido and changes in menstrual patterns may occur. Because kidney function could be compromised, patients with severe heart failure should be instructed to have their serum potassium concentrations and kidney function measured at 3 days and 1 week after initiating therapy with spironolactone and with every increase in dose, then every 2–4 weeks for 3 months, then every 3 months for a year, then every 6 months thereafter. If serum creatinine is >4 mg/dL or serum potassium is >5 mEq/L, interrupt or discontinue therapy. Spironolactone should be avoided in patients with kidney disease or conditions associated with hyperkalemia.[21]

HIRSUTISM AND HYPERTRICHOSIS

Both hirsutism and hypertrichosis are patterns of excessive hair growth that may be highly distressing to patients. Hirsutism occurs only in women and involves excessive growth of hair with masculine characteristics or “male-like” pattern of hair growth on the body and face, usually as a result of excessive androgenic stimulation. The effects of androgens on the hair follicles differ based on the body site. Androgen excess can lead to suppression of growth of scalp hair as excess androgens cause androgen-sensitive hair follicles to shorten during the anagen phase, resulting in miniaturization of the scalp hair, less scalp coverage, and alopecia. Conversely, androgen excess can cause hair growth in women in a pattern consistent with androgen-sensitive areas such as the face, axilla, pubis, chest, buttocks, lower back, abdomen, inner thighs, and shoulders. This is primarily due to increased sensitivity of the pilosebaceous units to androgens. Androgen excess can also cause acne and menstrual irregularities.[216,232-234]

In contrast, hypertrichosis is excessive hair growth that is independent of androgen influence. Hypertrichosis describes hair growth on any part of the body that is in excess of the amount that is usually present in persons of the same race, sex, and age. The hair growth is manifested by the uniform and superfluous growth of vellus (nonterminal) hair over the body, particularly in nonsexual areas. Unlike hirsutism, hypertrichosis can occur in both men and women. Drug-induced hirsutism can be induced by androgenic drugs, while drug-induced hypertrichosis usually is not associated with androgen production.[1,6,161,235,236]

CAUSATIVE AGENTS

HIRSUTISM

Drug-induced hirsutism is caused by androgenic agents such as danazol, testosterone, adrenocorticotropic hormones, and glucocorticoids (**Table 9-9**).[6,18,19,23,25,177,198,201,203,217,235-242] Hirsutism has been reported in 0.1% of women taking oral contraceptives. Hair growth has been reported on the face and is most likely caused by the progestin component. It may take some time for the hair growth to resolve following discontinuation. Hormone-replacement therapies containing moderate-to-high amounts of progestin are more likely to induce hirsutism.[177,235]

Valproic acid was shown in one prospective longitudinal trial in Indian women to increase serum testosterone concentrations and lead to polycystic ovary syndrome (POS). The incidence of hirsutism associated with valproic acid was

20%.[217,241] It is debatable as to whether phenytoin, high dose glucocorticoids, and acetazolamide induce hirsutism versus hypertrichosis; these drugs are reported in the literature to cause hirsutism or hypertrichosis via an unknown mechanism.[6,18,19,201,217,236,239,240] Cyclosporine and minoxidil are often listed in the nondermatological literature as causes of hirsutism (technically drug-induced hypertrichosis as this hair growth is independent of androgen influence).[217,242]

HYPERTRICHOSIS

Drugs associated with hypertrichosis are listed in **Table 9-10**.[6,18,19,21,201,217,235,238,243-269] The primary drugs known to cause hypertrichosis are cyclosporine, phenytoin, and oral and topical minoxidil. Other agents reported to induce hypertrichosis include diazoxide, erythropoietin, penicillamine, and psoralens.[18,235] Ophthalmic prostaglandin analogs have been well documented to cause hypertrichosis.[261] Drug-induced hyperprolactinemia can induce unwanted hair growth.[270]

Cyclosporine-induced hypertrichosis usually occurs within the first 3 months of therapy, generally peaks at about 6 months and is dose dependent.[260] Patients taking cyclosporine for prevention of rejection following organ transplantation at doses as high as 6 mg/kg/day are at higher risk (30–60%) for hypertrichosis versus only a 3% risk when taking lower doses (<5 mg/kg/day) for dermatological diseases.[6,201,271,272] Children and adolescents are at higher risk of developing moderate-to-severe hypertrichosis associated with cyclosporine than adults. Children experience excessive hair growth on the scalp, arms, legs, upper lip, parotid area of the face, eyebrows, ear lobes, nose, and back of neck. In addition, adults experience increase in body hair. The condition is reversible upon discontinuation of therapy, but it may take months for complete resolution.[260]

Long-term phenytoin therapy has been well documented as a cause of hypertrichosis (**Figure 9-3**), which typically occurs approximately 2–3 months after the initiation of therapy.[19] The limbs and sometimes the face and trunk are the most commonly affected areas. Hypertrichosis is reversible upon discontinuation of the drug. Dose reduction, when possible, may attenuate abnormal hair growth.[246]

Both oral and topical minoxidil cause hypertrichosis that primarily affects the malar areas, forehead, and sides of the face. Facial hypertrichosis is believed to be due to a systemic effect or via the transfer of the drug from the hands.[13] Hypertrichosis may disappear after approximately 1 year, even if the medication is continued, and usually resolves in 1–6 months if minoxidil application is discontinued.[193] Diazoxide can also lead to hypertrichosis that is often observed within a few weeks of initiating therapy and is more severe on the face and limbs. Diazoxide-induced hypertrichosis is reversible, but resolution can take as long as 2 years.[6,241] Erythropoietin, when used in patients with chronic kidney disease, can induce hypertrichosis. Erythropoietin-induced hypertrichosis is reversible upon discontinuation of therapy.[6]

Table 9-9 Agents Implicated in Drug-Induced Hirsutism[6,18,19,24,25,177,198,201,203,217,235-242]

Drug	Incidence	Level of Evidence[a]
Acetazolamide[236,c]	NK	C
Betamethasone[6,19,c]	NK	C
Carbamazepine[18,201,237]	NK	C
Cortisone[6,19,c]	1–10%	C
Corticotropin (adrenocorticotropic hormone)[6,18,19,201,238]	NK	C
Danazol[6,18,201,239]	NK	A
Dehydroepiandrosterone (DHEA)[216,240,217]	NK	C
Dexamethasone[6,19,c]	NK	C
Fludrocortisone[6,19,c]	NK	C
Fluoxymesterone[18,177,201,203,235]	NK[b]	C
Hydrocortisone[6,19,c]	NK	C
Methylprednisolone[6,19,c]	NK	C
Methyltestosterone[18,177,201,203,235]	NK	C
Metoclopramide[198]	NK	C
Metyrapone[201]	NK	C
Nandrolone[6,18,201]	NK	C
Oral contraceptives/hormones with androgenic activity[18,177,201,217,235]	NK[b]	C
Oxandrolone[18,177,201,203,235]	NK	C
Oxymetholone[6,18,201]	NK	C
Phenytoin[19]	NK	C
Prednisolone[6,19,c]	NK	C
Progesterone[6,19,24,201]	NK	C

Stanozolol[6,18,201]	NK	C
Testolactone[18,25,177,201,203,235]	NK	C
Testosterone[18,177,201,203,235]	NK	C
Triamcinolone[6,19,c]	NK	C
Valproic acid[217,241]	NK	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Believed to be common in susceptible women.

[c] It is debated as to whether acetazolamide, glucocorticoids, and phenytoin cause hirsutism versus hypertrichosis.

Vaccines have been reported to cause hypertrichosis. This may be due to a rare hypersensitivity reaction to aluminum-containing antigen solutions and the aluminum hydroxide in the vaccines. Affected areas often develop nodules with hyperpigmentation, hypopigmentation, hypertrichosis, and lichenification.[273]

Table 9-10 Agents Implicated in Drug-Induced Hypertrichosis[6,18,19,21,201,217,235,238,243-269]

Drug	Incidence	Level of Evidence[a]
ANTIHYPERTENSIVES		
β-blockers[18,201]	NK	C
Diltiazem[6,18]	NK	C
Minoxidil[243,244]	80% (oral)[245,246] 22–46% (topical)[247]	A
Nifedipine[18,201]	NK	C
Verapamil[6,18,201]	NK	C
ANTICONVULSANTS		
Phenytoin[6,18,248,249,250,251,252,253]	8.5–12%	A
ANTIVIRAL AGENTS		
Acyclovir[254]	NK	C
Zidovudine[6,18,201,238]	NK	C
CHELATING AGENT		

Penicillamine[6,18,19,235]	NK	C
CANCER CHEMOTHERAPY AGENTS		
Cetuximab[21,255,256]	1–10%	C
Erlotinib[257] (eyelash trichomegaly; hypertrichosis)	1–10%	C
Everolimus[21]	1–10%	C
Sorafenib[258]	NK	C

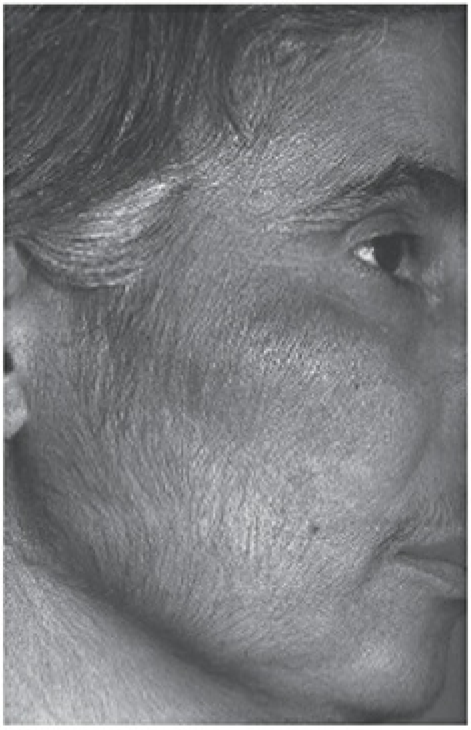

FIGURE 9-3 Hypertrichosis Caused by Phenytoin[19]

Source: Reproduced with permission from Bork K, ed. *Cutaneous side effects of drugs*. Philadelphia, PA: Saunders; Copyright©1988:249-58.

Ophthalmic agents used to treat glaucoma that contain prostaglandin F analogs such as latanoprost, bimatoprost, and travoprost can induce trichomegaly of the eyelashes and can also darken the eyelashes. In one case report, latanoprost promoted the regrowth of eyelashes in a patient suffering eyelash loss due to alopecia.[261]

EPIDEMIOLOGY

The overall incidences of drug-induced hirsutism and hypertrichosis are unknown. The incidences of hirsutism and hypertrichosis associated with specific drugs, where known, are presented in Table 9-9 and Table 9-10.[6,18,19,21,23,25,177,198,201,203,217,235-269] Although neither drug-induced disease is considered to occur commonly, these are well-recognized complications associated with drugs such as anabolic steroids, cyclosporine, and minoxidil.[241] When minoxidil is taken orally for at least 1 month, over 80% of patients experience reversible hypertrichosis.[6] Topical minoxidil has been reported to cause hypertrichosis in 3–5% of women using the 2% solution and in more than 5% of those using the 5% solution.[245,247] Erythropoietin has been reported to cause hypertrichosis in 13% of patients with chronic kidney disease. With the lower cyclosporine doses used in the treatment of dermatologic diseases, the risk of hypertrichosis declines to approximately 3%.[6] The incidence of drug-induced hypertrichosis associated with diazoxide in children treated for idiopathic hypoglycemia is nearly 100%. Two investigators reported incidences of hypertrichosis of 2% and 6% in children receiving phenytoin. Another study found that 35% of children experienced hair growth; however, this report included cases in which only moderate hypertrichosis occurred.[274] Hirsutism is known to affect 5–15% of women, but drugs are not a frequent cause.[216] Drug-induced hypertrichosis appears to be less common than hirsutism except in the treatment of organ transplantation with cyclosporine therapy, during which drug-induced hirsutism is manifested in 30–60% of patients.

MECHANISMS

HIRSUTISM

Terminal hair (coarse, longer, pigmented hair) is found primarily on the scalp and eyebrows. Vellus hair is the short fine, unpigmented hair found in all other areas. As androgen concentrations increase during puberty, the vellus hair of androgen-sensitive follicles is converted to terminal hair. Exposure to exogenous androgens such as testosterone can also cause vellus hair to be converted to terminal hair resulting in drug-induced hirsutism (**Table 9-11**).[18,19,177,201,216,217,235-239,242,275-277] Nondrug-related hirsutism is commonly associated with hormonal abnormalities associated with POS. Hirsutism involving virilization, especially in women over 25 years of age, is commonly associated with an androgen-producing tumor. Drug-induced androgenic stimulation of hair follicles is a less common cause of hirsutism.[33,58,278-281] Hyperinsulinemia can also lead to hirsutism via inhibition of aromatase, the enzyme that converts testosterone to estrogen. Valproic acid can cause hirsutism by provoking hyperinsulinemia.[278]

HYPERTRICHOSIS

Although mechanisms of hypertrichosis are not well understood, it is, by definition, not associated with androgen excess or exposure to androgenic agents. The disorder is not common and describes an increase in nonsexual hair. Hypertrichosis may be congenital (e.g., Hurler syndrome, fetal alcohol syndrome, or trisomy 18 syndrome), or associated with anorexia nervosa, malnutrition, hypothyroidism, porphyria, epidermolysis bullosa, dermatomyositis, or following skin trauma. It also can be caused by drugs that stimulate hair growth.[241,270,274] Hair growth induced by erythropoietin may be caused by a decrease in plasma cortisol concentrations. At higher serum concentrations, cortisol has been shown to inhibit follicular activity. Many antipsychotic agents are known to cause hyperprolactinemia, which can indirectly cause hypertrichosis. The mechanism of cyclosporine-induced hypertrichosis is unknown and appears to be independent of androgens as the hair grows in nonandrogen dependent sites and no other androgen effects are present like virilization. Pre- and postcyclosporine treatment studies showed no significant difference in testosterone, DHEA, and hydroxyprogesterone concentrations. Cyclosporine may exert its effect on skin structures as it is highly lipophilic and accumulates in the skin.[241] The proposed mechanism of diazoxide-induced hypertrichosis involves altered cutaneous blood flow leading to changes in hair growth.[241]

Table 9-11 Mechanisms of Drug-Induced Hirsutism and Hypertrichosis[18,19,177,201,216,217,235-239,242,275-277]

HIRSUTISM DRUGS	Mechanism
Acetazolamide[236]	Androgenic activity
Androgens/anabolic steroids[18,177,216,217,235,239,275,276]	Androgenic activity
Carbamazepine[18,201,237]	Androgenic activity
Contraceptives/hormones with androgenic activity[18,177,216,217,235,239,275,276]	Androgenic activity
Corticosteroids[18,201,217,235]	Androgenic activity
Corticotropin (adrenocorticotropic hormone)[18,19,238]	Androgenic activity
Metoclopramide[216]	Androgenic activity
Phenytoin[19]	Androgenic activity
Valproic acid[216,217,242,277]	Androgenic activity
HYPERTRICHOSIS DRUGS	
All offending agents	Stimulates hair growth[a]

[a] Mechanism is unknown.

Several underlying pathologic conditions are associated with acquired generalized hypertrichosis, such as human immunodeficiency virus-infection (HIV) and acquired immunodeficiency syndrome (AIDS). Patients with HIV or AIDS can experience eyelash trichomegaly or a generalized form of hypertrichosis. The pathogenesis remains unknown but may be multifactorial, associated with malnutrition, metabolic changes, and immunologic dysregulation, such as elevated serum interferon concentrations. In addition, drugs such as interferon and zidovudine may contribute to hypertrichosis.[235]

Hypertrichosis can appear after a head injury or other cerebral disturbances. Hypertrichosis was originally attributed to phenytoin therapy administered following head injury, but hypertrichosis has also occurred in patients with head injury who have not received phenytoin. Malnutrition and anorexia nervosa may, in rare instances, lead to hypertrichosis. Excessive hair growth of the limbs and trunks has been recorded in children with celiac disease as well as in young women on low-carbohydrate diets.[282] These acquired conditions as well as conditions such as juvenile hypothyroidism and malignancy are rare causes of hypertrichosis, and the mechanism is not fully understood.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

HIRSUTISM

Signs and symptoms associated with drug-induced hirsutism and hypertrichosis are listed in **Table 9-12**.[216,217,235] Women with drug-induced hirsutism present with excessive hair growth in a somewhat masculine pattern, such as the appearance of coarse facial hair in the upper lip or chin area. The chest, lower abdomen, back, and limbs also may be affected.[283] Patients with hirsutism often present with other dermatologic symptoms of virilization, such as acne, androgenetic alopecia, and seborrhea oleosa.[6] A physical examination typically facilitates differentiation between hirsutism and hypertrichosis. The Ferriman–Gallwey scoring system for hirsutism (**Figure 9-4**), which evaluates hair growth in nine body areas, can be helpful.[216,217,284] The nine body areas that are androgen-sensitive are graded from 0 (no terminal hair) to 4 (frankly virile) to obtain a total score. A normal score is less than 8.[216,217,274,284] A careful medication history should be obtained, and patients should be questioned regarding the onset and progression of hair growth, family history of similar disorders, exposure to skin irritants, menstrual and reproductive history, presence of hair loss, acne, and any changes in extremity or head size, facial contour, or weight.[33,216,217,274]

Table 9-12 Signs and Symptoms Associated with Drug-Induced Hirsutism and Hypertrichosis[216,217,235]

Hirsutism

- The development of larger, curlier, and darker hair in a male pattern; examples of sexual hair: mustache, beard, inner thighs, chest, back, buttocks area, and/or abdomen found on women
- Ferriman–Gallwey score[a]: score of 8 or higher

May be associated with

- Elevated serum testosterone concentration; the normal upper limit for total plasma testosterone concentrations in women is 70–90 ng/dL
- Insulin resistance
- A total plasma testosterone concentration that is normal or marginally elevated (within approximately 20 ng/dL of the upper limits of normal) in the absence of other features of concern (polycystic ovary syndrome, risk of neoplasm, risk of endocrinopathy, thyroid dysfunction, metabolic syndrome) probably indicates idiopathic hirsutism or idiopathic hyperandrogenism
- Pelvic ultrasonogram: polycystic ovaries or neoplasm
- Menstrual irregularities
- Metabolic syndrome (central obesity, hypertension, glucose abnormalities, and dyslipidemias)

Hypertrichosis

- Hair growth is distributed in a generalized, nonsexual pattern on men or women; the hair involved may be vellus, lanugo, or terminal hair
- Hair growth normally involves face, limbs (front and back), eyelashes, elbows, pinnae auris, elbows, anterior or posterior neck, lumbosacral region or trunk
- Ferriman–Gallwey scale[a]: score of <8
- No elevation in free testosterone concentrations following start of hypertrichosis-inducing agent
- No laboratory test evaluation required

---

[a] See Figure 9-4 for the Ferriman–Gallwey scoring system for hirsutism.[216,217]

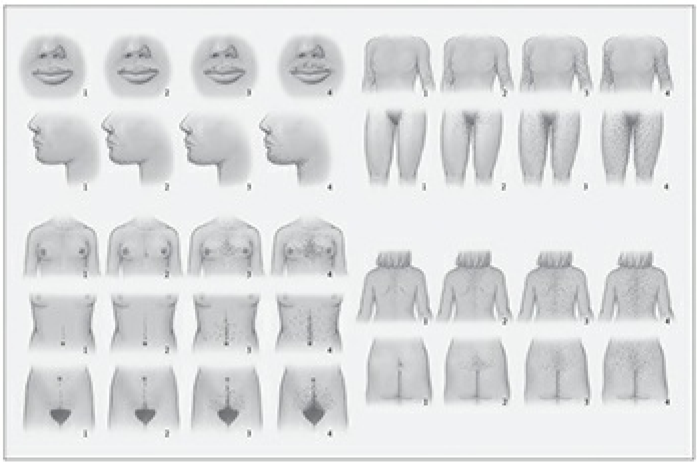

FIGURE 9-4 The Ferriman–Gallwey Scoring System for Hirsutism[216,217]

Source: Rosenfield RL. Hirsutism. *N Engl J Med.* 2005; 353:2578-88. Copyright© Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.

During evaluation of hirsutism, it is important to rule out nondrug causes such as POS, ovarian tumor, adrenal tumor, hyperprolactinemia, congenital adrenal hyperplasia, Cushing syndrome, diabetes, and thyroid disease.[33,216,217,274,285] In particular, in women with epilepsy who present with hirsutism, POS should be excluded. POS is characterized by hyperinsulinemia due to insulin resistance, which promotes androgen production. Women with epilepsy have a higher incidence of POS and higher plasma androgen concentrations, which medications may further exacerbate. Laboratory evaluations for patients with hirsutism should include measurement of serum total and unbound testosterone, DHEA, DHEA sulfate (DHEA-S), follicle-stimulating hormone, luteinizing hormone, and prolactin concentrations. An ovarian tumor is considered when the total serum testosterone concentration is >200 ng/dL in the presence of a mildly elevated DHEA-S concentration.[177] For drug-induced hirsutism, the history of hair growth is very important in determining whether androgenic drugs have been used because most androgenic drugs are not detected by testosterone assays except for valproic acid, which increases plasma testosterone concentrations.[217] Drug-induced hirsutism should be suspected in female patients with hair growth exhibiting masculine characteristics who have been exposed to drugs known to have androgenic effects. Conditions to consider in the differential diagnosis of drug-induced hirsutism and hypertrichosis are listed in **Table 9-13**.[177,241,285,286] In addition, specific diagnostic tests that can be used to differentiate drug-induced hirsutism from other causes of hirsutism are listed in **Table 9-14**.[270,274]

Table 9-13 Conditions to Consider in the Differential Diagnosis of Drug-Induced Hirsutism and Hypertrichosis[177,241,285,286]

- Adrenal tumor
- Congenital adrenal hyperplasia
- Cushing syndrome
- Diabetes
- Familial
- Hyperprolactinemia
- Idiopathic
- Insulin resistance
- Ovarian tumor
- Polycystic ovary syndrome
- Thyroid disease

Table 9-14 Clinical and Diagnostic Evaluation of Hirsutism[245,248,270-274]

Diagnosis	Abnormal Laboratory Values		Other Tests
Drugs/familial/idiopathic	Laboratory values are within normal limits		
Congenital adrenal hyperplasia	Cortisol	Low to normal	ACTH stimulation test can be helpful for diagnosis
	DHEA-S	High to normal	
	Testosterone	High to normal	
	17-α-hydroxyprogesterone	High	
Polycystic ovary syndrome	Follicle-stimulating hormone	Low to normal	Insulin, glucose, and lipid concentrations
	Luteinizing hormone prolactin	Normal to high	
	Testosterone	Normal to high	
Tumors • Adrenal tumor • Ovarian • Pituitary	Cortisol	High	Imaging[a]
	DHEA-S	Normal to high	
	Testosterone	High	Imaging[a]
	Testosterone	High	Imaging[a]
	Prolactin	High	

ACTH = adrenocorticotropic hormone, DHEA-S = dehydroepiandrosterone sulfate.

[a] Plasma prolactin concentrations may be high if drug-induced (e.g., risperidone) hyperprolactinemia is present. May need venous catheterization to help identify a tumor when imaging is negative in the face of strong clinical suspicion.

HYPERTRICHOSIS

In patients with hypertrichosis, the excessive hair growth involves terminal and/or vellus hair and a nonmale pattern of hair growth is noted on areas of the body where the hair is normally short. Hypertrichosis may be generalized or circumscribed and is independent of hormone stimulation.[6] Examples of hypertrichosis in a male patient include hair in the forehead area or coarser, prominent hair on one area of the shoulder or forearm.[283] Drug-induced hypertrichosis should be suspected in male or female patients who exhibit abnormal growth of nonsexual hair (nonandrogen-dependent hair) and who are taking potentially causative drugs that are not associated with increased androgenic activity.[217,240,241] Drug-induced hypertrichosis usually becomes apparent within a few weeks to a few months following initiation of therapy.[6,19,235,287] Diazoxide induces hair growth within a few weeks after initiation of treatment.[6] Phenytoin-induced hypertrichosis may not appear until after 2–3 months of therapy.[287] Topical minoxidil induces hair growth after approximately 4 months of therapy, whereas systemic minoxidil causes hypertrichosis within a few weeks of treatment initiation.[6,235] Hypertrichosis induced by cyclosporine may become evident within the first month of therapy, but symptoms generally worsen over the first 6 months of therapy before remaining constant.[241] After the offending drug is stopped, hypertrichosis resolves within several months to 1 year depending on the hair cycling characteristics of the affected site (i.e., if face is involved, resolution generally occurs within 3 months; resolution of hypertrichosis involving the arms requires approximately 1 year).[235]

RISK FACTORS

Women who are already at risk for hirsutism from other causes, such as menopause, pregnancy, excessive ovarian androgen production, family history of hirsutism, and those of Mediterranean origin may be at greater risk of hirsutism or experience more pronounced hirsutism when exposed to medications with androgenic effects.[276,282,283,285] Risk factors for drug-induced hirsutism are summarized in **Table 9-15**.[177,216,235,270,283,286]

Table 9-15 Risk Factors for Drug-Induced Hirsutism[177,216,235,270,283,286]

- Female sex
- Drug administration
    - Higher doses
    - Intravenous route
    - Longer duration of exposure
- Combination of two or more drugs that can cause hair growth
- Cushing syndrome, hyperprolactinemia, acromegaly, thyroid dysfunction, and tumors
- Drug interactions that lead to increased serum concentrations of drug that cause hirsutism
- Endocrine abnormalities, such as insulin resistance
- Female patients already at risk for hirsutism
- Genetic predisposition
- Hormonal abnormalities, such as menstrual irregularity, endometrial cancer, polycystic ovary syndrome, infertility
- Metabolic abnormalities, such as metabolic syndrome often involving central obesity, hypertension, glucose abnormalities, and dyslipidemia

Drug dose and duration of therapy can be risk factors for drug-induced hirsutism and hypertrichosis, as some drugs induce hair growth only at higher doses and following long-term exposure. For instance, the risk of hypertrichosis associated with cyclosporine is lower in patients taking smaller doses for the management of dermatologic diseases compared with patients taking higher doses for other indications.[6] The addition of tretinoin solution to topical minoxidil therapy leads to increased absorption of minoxidil and an associated increased risk of hypertrichosis.[288] Children and adolescents appear to be at greater risk for cyclosporine–induced hypertrichosis than adults.[241]

In prepubertal children, hypertrichosis is typically not associated with an underlying endocrine disorder but is commonly an adverse effect of drug administration.[289] Concomitant administration of two or more drugs known to cause abnormal hair growth increases the risk, as do drug interactions that lead to increased serum concentration of a hirsutism-provoking drug. Increased serum concentrations of drugs that induce hypertrichosis usually increase the risk; however, psoralen-induced hypertrichosis appears not to be dose-related.[241,274] **Table 9-16** summarizes risk factors for drug-induced hypertrichosis.[18,235,241,283]

Table 9-16 Risk Factors for Drug-Induced Hypertrichosis[6,235,241,283]

- Drug administration
    - Higher doses
    - Intravenous route
    - Longer duration of exposure
- Combination of two or more drugs that can cause hair growth
- Drug interactions that lead to increased serum concentrations of drug that cause hypertrichosis
- Acquired immunodeficiency syndrome
- Anorexia nervosa
- Familial trait or congenital
- Head injuries and other cerebral disturbances
- Hepatic porphyria caused by chemical exposure such as hexachlorobenzene
- Juvenile dermatomyositis
- Juvenile hypothyroidism
- Malignancy
- Malnutrition

MORBIDITY AND MORTALITY

Drug-induced hirsutism and hypertrichosis, while often unpleasant, are not associated with increased morbidity or mortality.

PREVENTION

Drug-induced hair growth is best prevented by avoiding the use of agents known to cause hirsutism or hypertrichosis, especially in patients with pre-existing risk factors. Patients should not be exposed to two or more drugs with a known potential to cause abnormal hair growth unless absolutely necessary. Lower doses and shorter periods of exposure to potentially causative drugs are also advised.[6] Using a contraceptive medication with a lower progestin content may be of benefit in reducing the risk of hirsuitism.[19] The potential for minoxidil-associated hypertrichosis is increased if the topical solution is accidentally transferred to the face from the hands or from residual minoxidil on pillows, bed sheets, and garments. Topical minoxidil also may be distributed via local intravascularization, but this is not normally preventable.[193,283,287] Avoiding drug interactions that lead to increased serum concentrations of drugs that cause hirsutism or hypertrichosis is also important, especially if the hirsutism or hypertrichosis is dose-dependent. **Table 9-17** provides some approaches to help prevent drug-induced hirsutism and hypertrichosis.[18,235,241,274,283]

Table 9-17 Approaches to Help Prevent Drug-Induced Hirsutism and Hypertrichosis[18,235,241,274,283]

- Avoid drugs with potential to induce hirsutism or hypertrichosis when possible
- Use the lowest possible dose of the potentially causative agent
- Avoid, when possible, the use of multiple drugs with the potential to cause hirsutism or hypertrichosis
- Limit the duration of exposure
- Use the oral route rather than the intravenous route whenever possible
- Avoid drug interactions that could increase serum concentrations of drugs with the potential to cause dose-dependent hirsutism or hypertrichosis; adjust appropriately doses of renally-eliminated or hepatically-metabolized drugs with the potential to cause hirsutism or hypertrichosis in patients with kidney or liver disease, respectively
- Identify any family history of androgenetic alopecia, hirsutism, amenorrhea, or infertility prior to initiating therapy with medications known to cause hirsutism or hypertrichosis to allow the clinician to identify and correct potential risk factors

MANAGEMENT

HIRSUTISM

Medications for managing hirsutism include those that inhibit androgen action at the hair follicles and suppress androgen production. Response to these medications is very slow, and desired effects may not be evident for 6 months or more; consequently, hair removal techniques may also be warranted. Clinical management of drug-induced hirsutism includes discontinuing the causative agent, if possible, administering topical pharmacological treatment, using cosmetic procedures for hair removal, using light sources and lasers for hair removal, and administering oral systemic drug therapy (oral contraceptives, antiandrogens, 5α-reductase inhibitors).[235]

A detailed list of the topical and nonpharmacologic procedures for the treatment of both hirsutism and hypertrichosis is provided in **Table 9-18**.[216,235,244,290] Systemic agents used for the treatment of hirsutism are listed in **Table 9-19**.[161,186,211,216]

Table 9-18 Cosmetic Measures for Management of Hypertrichosis and Hirsutism[216,235,244,290]

Cosmetic Measure	Information
Bleaching	Commercial products contain persulfate to boost peroxide bleach but can lead to anaphylaxis Home product: 40 mL hydrogen peroxide + 7 mL 20% ammonia Apply to hair and leave on hair until the color is removed (average time is 5–10 minutes) Duration of effect: Up to 4 weeks Disadvantages: Does not work well for dark-skinned patients; skin irritation
Chemical depilatories	Chemicals that damage the hair leading to breakage at the skin's surface Thioglycolates are commonly used in concentrations of 2–4% and act within 5–15 minutes Duration of effect: ～1 week Disadvantage: Potent skin irritant; not for use in children unless for small localized sites to avoid toxicity from systemic thioglycolate absorption Adverse effects: Skin irritation, allergic contact dermatitis, and, with inadvertent eye contact, corneal alkali burns
Electrosurgical epilation	Three types of electrolysis: Galvanic electrolysis; thermolysis electrolysis; blend method of electrolysis (considered the most effective) Considered a permanent mode of hair removal Target: Localized coarse hair Duration of effect: Hair regrows in 20–40% of the follicles treated Disadvantage: Expensive, painful, requires multiple treatment sessions and is time-consuming Adverse effects: Hyperpigmentation or hypopigmentation, perifollicular inflammation, punctate scarring
Light source and laser treatments	Several effective systems available: Ruby laser, alexandrite laser, diode laser, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, and intense pulsed-light sources (590–1,200 nm) Longer pulse durations and longer wavelength lasers such as the Nd:YAG laser should be used on dark skin to lessen risk of scarring or dyspigmentation; these lasers are less efficacious but involve less risk to skin; pulsed diode lasers are generally more reliable and less expensive than other laser sources for hair removal; Q-switch YAG lasers are optimal for darker skinned patients; however, they are ineffective for permanent hair removal Duration of effect: Permanent hair removal often occurs primarily in patients with dark hair after multiple treatments, although hyperpigmentation is a risk Patients with blonde, red, or white hair may not have permanent hair removal, but the regrowing hairs are thinner and more lightly pigmented Disadvantages: Cost and rare adverse reaction of thermal damage-related cutaneous side effects (blistering, crusting, scabbing, pigmentary alteration, scarring); if occurs, this usually requires treatment with topical corticosteroid or topic antibiotic

	Adverse effects: Pain/discomfort (icing treated areas postprocedure is helpful); immediate perifollicular edema and mild erythema, which lasts ~minutes to hours following treatment
Plucking	Appropriate for targeting only small areas, as it is painful, slow, and tedious Duration of effect: Up to 2 weeks Adverse effects: Hyperpigmentation; folliculitis, distorted hair follicles, scarring Risk of metaplastic ossification
Shaving	Does not affect the rate or width of regrowth; it will, however, result in stubble that grows out without the softer and finer unshaven hair tip Duration of effect: 24 hours Disadvantages: Requires daily shaving; skin irritation
Topical hair growth retardant (cell-cycle inhibitor)	Eflornithine hydrochloride, 13.9%; topical cream applied twice daily; slows excessive hair growth but does not remove excessive hair; noticeable results take about 6–8 weeks; patients must also use hair removal methods Clinical trials have shown efficacy for facial hirsutism improvement Target: Facial areas of unwanted hair growth Contraindications: Pregnancy, breastfeeding Disadvantages: Expensive; hair grows back after discontinuation; must use hair-removal techniques Adverse effects: Burning, stinging, acne, rash may occur at application site
Trimming	Does not accelerate hair regrowth Good option for young children with either local or generalized hypertrichosis Duration of effect: ~24 hours or longer Disadvantage: Hypertrichosis may still be noticeable
Waxing	Cold, warm, or hot wax is applied to the area of unwanted hairs; then the wax is stripped off, thus epilating the embedded hairs Target: Any vellus hairs in all areas of the body Duration of effect: 2–6 weeks Disadvantage: Poor results when attempting removal of short hair Adverse effects: Pain, skin irritation, folliculitis

If the offending medication can be discontinued, then no treatment is needed if the excess hair growth is mild. Discontinuation of therapy with some drugs (e.g., cortisol) usually leads to resolution of hirsutism.[29] However, drug-induced hirsutism is not always reversible, and resolution, when it does occur, may require longer than 6 months after discontinuation of therapy. In this case, if the hair growth is moderate to severe, or if the patient cannot tolerate even mild hirsutism, short-term use of cosmetic procedures, topical pharmacologic treatment for hair removal, or both may be desirable.

If the causative agent cannot be discontinued, a variety of treatment options exist. Nonsystemic drug treatment is appropriate for mild hirsutism. For patients with moderate-to-severe hirsutism or those with mild hirsutism who desire more aggressive treatment, systemic therapy should be considered along with nonpharmacologic and topical treatments. Weight loss in overweight women can decrease serum concentrations of androgens and lessen hirsutism.[270]

Measures include bleaching, wax stripping, shaving, plucking (tweezing), using hair-removal creams (depilatories), and electrolysis. The FDA has approved electrolysis as an option for permanent hair removal, because it has been associated with a 30% reduction in the number of hair follicles. Laser therapy is a newer development, and several types are available, including the ruby, alexandrite, pulsed diode, and Q-switched yttrium-aluminum-garnet (YAG) lasers. Pulsed-diode lasers are often more reliable and less expensive than other laser sources for hair removal. Q-switched YAG lasers work best for darker-skinned patients with dark hair. Unfortunately, laser therapy is not always effective for long-term hair removal. After a single laser treatment, hair growth is delayed for 2–6 months, and hair removal is permanent in some patients after multiple treatments. The cost of these approaches is sometimes an issue, because most patients require repeated treatments.[216,270,280]

Oral contraceptives containing lower amounts of androgenic progestins (e.g., norgestimate desogestrel, ethynodiol diacetate, gestodene, and norethindrone acetate) are preferable for the management of mild to moderate hirsutism. This treatment should reduce the need for shaving by 50% and can usually arrest the progression of hirsutism but will not reverse it.[216] Women with clinically significant hirsutism may require therapy with an androgen-inhibiting agent either as monotherapy or in addition to oral contraceptive treatment.[216,219,222,227] The addition of the oral contraceptive ensures menstrual cycling and minimizes the risk of pregnancy, as antiandrogens and α_2-reductase inhibitors are teratogenic.[216] It has been reported that combined therapy with an oral contraceptive and an androgen-receptor inhibitor may produce clinical improvement in up to 75% of women with hirsutism.[270]

Table 9-19 Common Medications Used for Treatment of Hirsutism[21,161,186,211,216,217]

Type of Therapy	Agent	Dose	Contraindications/ Precautions	Major Adverse Effects
Androgen inhibition	Spironolactone	50–100 mg orally twice daily (300 mg daily for pronounced hirsutism or for obese patients)	Lack of contraception, kidney disease, liver failure	Teratogenic; irregular menstrual bleeding unless oral contraceptive administered; decreased libido; nausea; hyperkalemia; hypotension; liver dysfunction
	Cyproterone (not available in the United States)	Induction: 50–100 mg orally at bedtime, days 5–15 of the menstrual cycle Maintenance: 5 mg orally at bedtime, days 5–15	Lack of contraception	Teratogenic; irregular menstrual bleeding unless estrogen administered cyclically; decreased libido; nausea
	Flutamide	125–250 mg orally twice daily	Lack of contraception; liver disease	Teratogenic; reserved for severe hirsutism because of hepatotoxicity
Androgen suppression	Ethinyl estradiol + drospirenone OR ethinyl estradiol + norgestimate OR ethinyl estradiol + ethynodiol diacetate (all low androgenic activity)	1 tablet orally at bedtime (higher estrogen doses may be necessary in heavier women for menstrual regularity)	Breast cancer, smoking, history of thrombosis, cardiovascular disease, uncontrolled hypertension	Irregular vaginal bleeding, venous thrombosis, bloating
5α-reductase inhibitors	Finasteride	1–5 mg orally daily	Lack of contraception	Teratogenic; minimal adverse effects in females
	Dutasteride	0.5–2.5 mg orally daily	Lack of contraception	Teratogenic; limited data on dutasteride use in hirsutism; minimal adverse effects in females
Other hormones	Glucocorticoids	Example: prednisone 5–7.5 mg orally at bedtime	Uncontrolled diabetes; obesity	Changes typical of Cushing syndrome; adrenal atrophy
	Gonadotropin-releasing agonists	Leuprolide acetate, depot suspension 7.5 mg monthly intramuscularly, with 25–50 mcg transdermal estradiol	Osteoporosis	Osteoporosis without estrogen-progestin replacement

Antiandrogenic drugs include spironolactone, flutamine, and cyproterone. Spironolactone and flutamine are the most widely used and are equally effective. Spironolactone is an aldosterone antagonist and appears to be the safest androgen-receptor inhibitor. Flutamide may cause hepatotoxicity, and liver function should be monitored in patients receiving this agent. Cyproterone is not available in the United States. Therapy with spironolactone or cyproterone often provides significant attenuation of hirsutism within 6 months and maximum benefit within 9–12 months.[216]

Other hormonal therapies include finasteride, a 5α-reductase inhibitor that has been shown to be effective for the treatment of hirsutism. However, finasteride is teratogenic, causing feminization in male infants exposed to finasteride during the first trimester; therefore, while not contraindicated in women of childbearing potential, finasteride is recommended only for women who are postmenopausal with no chance of becoming pregnant. If used in premenopausal women, measures must be implemented to prevent pregnancy. Finasteride is usually reserved for severe or refractory cases of hirsutism. Once initiated, treatment should be continued for at least 2 years for maximum benefit.[270,279] Combination therapy with finasteride and spironolactone demonstrated additive reduction in hirsutism scores.[286,291]

Dutasteride, also a 5α-reductase inhibitor, has not been extensively studied for the management of hirsutism. Other hormonal therapies include glucocorticoids and gonadotropin-releasing hormone agonists. The efficacy of glucocorticoids for drug-induced hirsutism is unknown. Gonadotropin-releasing hormone agonists are considered alternatives to oral contraceptives.[216]

Treatment with eflornithine, a topical hair growth inhibitor, has been shown to reduce rates of hair growth. Eflornithine therapy results in the reduction of the frequency of use of other methods of hair removal. Eflornithine is indicated for facial hirsutism and is marketed as an 11.5% topical cream that is applied twice daily. The cream is effective for slowing excessive hair growth but not for removing excess hair. The cream must remain on the skin for at least 4 hours. Unfortunately, if therapy is discontinued, hair growth will likely return.[177,235,282]

HYPERTRICHOSIS

Although drug-induced hypertrichosis nearly always resolves after discontinuation of therapy with the causative agent, reversal of hair growth takes time. During that period, cosmetic methods for hair removal are suggested and are effective (Table 9-18).[235,274,280] Consequently, the management of drug-induced hypertrichosis includes discontinuation of therapy with the offending agent, if possible, as well as nonsystemic approaches including cosmetic procedures for removal of excess hair; hair removal using light sources and lasers; and topical pharmacologic treatment.[235] Systemic therapy with agents such as antiandrogens or oral contraceptives should not be used. Treatment with eflornithine may be effective for hypertrichosis. See Table 9-19 for details on eflornithine.[161,186,211,216]

Cosmetic measures for the treatment of hirsutism include bleaching, wax stripping, shaving, plucking (tweezing), using hair-removal creams (depilatories), electrolysis and laser therapy. A discussion of these measures is provided in Table 9-18.[216,235,244,290]

INFORMATION FOR PATIENTS

Patients should have realistic expectations regarding the time frame for resolution of drug-induced hirsutism and hypertrichosis, and must understand that it may take a long time for these conditions to resolve even after therapy with the causative agent is discontinued. When certain medications are used to treat hirsutism, hormonal suppression for several months or longer may be necessary before reduction of hair growth becomes evident.[216,217,282] When oral drug therapy is used to manage hirsutism, patients should be instructed that treatment must continue during therapy with the causative agent. For patients with drug-induced hypertrichosis, when the offending drug is discontinued, resolution of excess hair growth may require several months to 1 year, depending on the hair-cycling characteristics of the site of hypertrichosis. For example, it takes an average of 3 months for hypertrichosis resolution if the excess hair growth is on the face but an average of 1 year if the excessive hair growth is on the arms.[235]

Patients with drug-induced hirsutism or hypertrichosis should be counseled regarding the potential benefit of cosmetic measures, and these can be encouraged even if oral therapy is prescribed. Patients should be informed of the cosmetic options available, their adverse effects, duration, effectiveness, and cost. Inform patients that although shaving can lead to a stubble-like hair, it does not worsen hirsutism. Depilating agents, though effective, can cause chronic skin irritation and may even worsen hair growth if used excessively or indiscriminately. Waxing or plucking in androgenized skin may lead to folliculitis and trauma to the hair shaft, and does not kill the hair follicles. Methods that can permanently destroy the hair follicle, such as electrolysis and laser, often work well, but require time to be effective. These methods may also be costly and usually require repeated treatments.[216,217,280]

Seizures

Timothy E. Welty

Seizures, including those induced by drugs, are serious neurologic events; without prompt and proper recognition, diagnosis, and treatment, seizures can result in permanent neurologic deficits. Drug-induced seizures can present as a single limited seizure event, convulsive status epilepticus, or nonconvulsive status epilepticus. It is important to rapidly recognize drug-induced seizures and to provide immediate, effective treatment.

CAUSATIVE AGENTS

Numerous drugs have been identified as possible causes of seizures. Because drug-induced seizures are relatively rare events, it is difficult to determine incidence and causality for many drugs. Most reports of drugs causing seizures are based on individual cases, epidemiologic studies, and very few prospective studies.[1] A list of drugs associated with seizures is presented in **Table 10-1**.[1-37]

Drugs can induce seizures in a number of clinical situations. The scenario that most people recognize is the setting of an intentional or unintentional overdose. Seizures can also occur as an adverse effect of a drug even when administered at therapeutic doses. These events are not predictable and may occur even in patients with no history of or risk factors for seizures. Abrupt discontinuation of therapy with some drugs can also result in a seizure. Many illicit drugs are associated with this type of seizure. In addition, ethanol, baclofen, antiepileptic drugs, and benzodiazepines may be associated with withdrawal seizures. Caution must be exercised when using an antagonist to one of these drugs because of the potential for precipitating a seizure.

EPIDEMIOLOGY

First-time seizures from all causes occur with an incidence of 70–100 per 100,000 individuals annually.[38] Of these, 23–61 per 100,000 are single events in patients in whom epilepsy does not develop. The mortality rate associated with a first unprovoked seizure is 1–4%. Limited data indicate that seizures as a toxic complication of drugs comprise approximately 6% of new onset seizures, and nearly 9% of cases with status epilepticus are related to drug toxicity.[39,40] The incidence of pediatric cases of drug-induced seizures was reported as 4.7% in an analysis of data from the Toxicology Investigators Consortium Case Registry.[41]

Table 10-1 Agents Implicated in Drug-Induced Seizures[1-37]

Drug	Incidence	Level of Evidence[a]
ANTIARRYTHMICS		
Lidocaine[1]	20–25%	A
Mexiletine[2]	NK	B
ANALGESICS		
Hydromorphone[3]	NK	C
Meperidine[4,5]	2.1%	B
Morphine[5]	NK	B
Naloxone[5]	NK	B
Nefopam[5]	NK	B
Tramadol[6,7]	13–50%	B
ANESTHETICS		
Propofol[8,9]	23–40%	B
Sevoflurane[10-12]	50–100%	A
ANTIBIOTICS		
		B

Carbapenems[13]	0.9%[b] 2–3%[c]	
Cephalosporins[14]	NK	B
Fluoroquinolones[3]	NK	B
Penicillins[14]	NK	B
ANTIDEPRESSANTS		
Bupropion[15,16]	0.5–4%	A
Tricyclic/tetracyclic antidepressants[16,17]	0.25–2%	A
ANTIEPILEPTIC DRUGS		
Benzodiazepines[3]	NK	B
Carbamazepine[18-20]	NK	A
Felbamate[21]	NK	B
Oxcarbazepine[12,18]	NK	C
Phenobarbital[3]	NK	B
Phenytoin[3]	NK	B
Topiramate[3]	NK	B

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Used alone.

[c] Used in combination with other antibiotics.

[d] In patients with brain metastases.

The precise incidences of seizures induced by specific drugs are unclear. One of the first reported studies on drug-induced seizures by the Boston Collaborative Drug Surveillance Program found a rate of 0.08% in 32,812 patients.[42] Another review of emergency cases of status epilepticus showed that ethanol ingestion and drug overdose were responsible for 13% and <5%, respectively, of these cases.[43] Twenty-five percent of the seizures related to a drug overdose were fatal. A review of 1993 data from the California Poison Control System showed that cyclic antidepressants, stimulants, antihistamines, theophylline, and isoniazid were the most common causes of drug-induced seizures.[44] A follow-up to this study 10 years later showed that the most common causes of drug-induced seizures were bupropion, diphenhydramine, cyclic antidepressants, tramadol, amphetamines, isoniazid, and venlafaxine.[45] Of patients included in this series, 68% had a single seizure, 27% had more than one seizure, and 3.6% experienced status epilepticus. In a study of drug-induced seizures among children, the most common causative agents were antidepressants and anticholinergics/antihistamines.[41] In this study, sympathomimetics were the most common causative drugs in children younger than 2 years old. However, these data are derived only from calls to poison centers or admissions to an emergency department and do not account for drug-induced seizures that occur outside these settings. Most likely, the incidence of drug-induced seizures is greater than is reflected in these reports. Even so, drug-induced seizures are relatively rare events that typically occur as a single, isolated seizure.

ANALGESICS

Tramadol is associated with drug-induced seizures. In a review of 190 cases of tramadol toxicity reported to a poison control center, 13.7% of patients experienced a seizure.[6] A similar study reported that 55% of patients with tramadol intoxication experienced a seizure.[7] Ninety percent of these seizures were single events, and 84% occurred within 24 hours of ingesting a toxic dose. Chronic use of tramadol predisposed these patients to a seizure. Most cases are associated with toxic doses or prolonged chronic use, but seizures are possible at therapeutic doses, especially in patients with underlying epilepsy.[7]

ANESTHETICS

Although propofol is used in the treatment of refractory status epilepticus, it is also associated with drug-induced seizures. Several case series have suggested that 24–40% of patients receiving propofol experience seizures or epileptiform electroencephalogram (EEG) activity during induction, emergence, and recovery from anesthesia.[8,9]

Sevoflurane is associated with a high incidence of drug-induced seizures. Studies of EEG activity during the induction of anesthesia have shown epileptiform activity in 50–60% of children and adults, and this increases to nearly 100% of patients when combined with hyperventilation and hypocapnia.[10,11] Additional study of EEGs in patients receiving sevoflurane has demonstrated a dose-dependent relationship in the EEG change.[12] At a 1.5 minimum alveolar concentration, epileptiform EEG discharges were present in 100% of patients.

ANTIBIOTICS

Carbapenems have been reported to cause seizures. Approximately 0.9% of patients taking imipenem as monotherapy experience a seizure.[13] The incidence of seizures in patients taking imipenem in combination with other antibiotics is 2–3%. In one study, 28% of $n = 21$ children treated with imipenem for bacterial meningitis experienced a seizure.[46] In contrast, meropenem caused no seizures in a study of adult patients with bacterial meningitis.[47] In another study, 12% of children receiving therapy with meropenem experienced a seizure.[48]

Cephalosporins are associated with neurotoxicity, with 10% of individuals with neurotoxicity experiencing convulsive seizures and another 10% having EEG-confirmed nonconvulsive status epilepticus.[49] About 50% of these cases were related to inappropriate dose adjustment in kidney disease. Penicillins have also been associated with seizures, typically in association with inappropriate dosing in patients with acute kidney injury or chronic kidney disease.[14]

There are several case reports of seizures associated with isoniazid, especially in children.[50] Reports of seizures with other antibiotics include quinolones and macrolides.[51] However, it is difficult to determine if the seizure resulted from the antibiotic or complications of an infectious process.

ANTICHOLINERGICS

In a study of drug-induced seizures in adults, nearly 10% of the cases were associated with ingestion of an anticholinergic agent.[44] A study in pediatric patients showed that 22% of children with drug-induced seizures had ingested an anticholinergic agent or antihistamine.[41] Diphenhydramine, chlorpheniramine, and doxylamine were the most common anticholinergic agents associated with drug-induced seizures in children.

ANTIDEPRESSANTS

Overdoses with tricyclic antidepressants are responsible for over 40% of seizures encountered in the emergency department.[17,52] Most of these seizures are generalized tonic-clonic seizures, but partial seizures may occur in individuals with a history of epilepsy.[42,45]

Other antidepressant agents can cause seizures in the setting of an overdose. Approximately 2% of patients with an overdose of a selective serotonin reuptake inhibitor experience a seizure.[53] Overdose of bupropion is also associated with a high incidence of seizures.[15]

Antidepressant drugs may also cause seizures at therapeutic doses. The incidence varies from approximately 0.1% with lower doses of imipramine to over 2% with higher doses of bupropion.[30] The risk of seizures appears lowest with trazadone, fluoxetine, and fluvoxamine. In contrast, the risk of seizures is highest in association with maprotiline, amoxapine, and bupropion, and these drugs should be avoided in patients with epilepsy. The risk of antidepressant-associated seizures is dose-dependent; for example, the incidence of seizures associated with bupropion at doses above 450 mg/day is 2–4%, while at lower doses the incidence is 0.5–1%.

ANTIEPILEPTIC DRUGS

Paradoxically, antiepileptic drugs have been associated with drug-induced seizures.[19-22] It is unclear if the seizures were due to an actual adverse event associated with the antiepileptic drug, a result of pre-existing seizures, due to an overdose of the antiepileptic drug, or breakthrough seizures following discontinuation of the antiepileptic drug.

ANTIFIBRINOLYTIC DRUGS

Although antifibrinolytic drugs are considered to be safe, seizures have been reported with their use.[54] Unlike aprotinin, tranexamic acid and EACA (ε-aminocaproic acid) are associated with seizures.[54] Most reports of seizures are in patients who are in the early postoperative period following cardiac surgery.[55,56] The incidence of seizures associated with tranexamic acid in retrospective studies is reported to be 0.5–1% with standard doses but increases to 6.4–7.3% with higher doses (>100 mg/kg). In a prospective study, the incidence of tranexamic acid-induced seizures was 3%. Seizures associated with tranexamic acid also have been reported in patients with kidney disease, other surgeries, and hemoptysis.

ANTIPSYCHOTICS

Among older antipsychotic agents, chlorpromazine is associated with the greatest risk of seizures, with an incidence of 2.1%.[28] At chlorpromazine doses <200 mg/day, 200–900 mg/day and >900 mg/day, the incidence of seizures is 0.3%, 0.7%, and 9%, respectively.[29] Concomitant treatment with other psychoactive agents increases the risk of chlorpromazine-induced seizures. Other older antipsychotic agents, such as trifluoperazine and thiothixene, are associated with a much lower risk of seizures than chlorpromazine.

Of the newer atypical antipsychotic agents, clozapine is associated with the greatest risk of seizures. The cumulative risk of seizures associated with clozapine over nearly 4 years of treatment has been estimated to be 10%.[31] At clozapine doses <300 mg/day, the incidence of seizures is approximately 1%, which increases to 4% at doses >600 mg/day.[32]

ANTINEOPLASTIC AGENTS

Approximately 13% of patients with cancer experience a seizure, and seizures account for 5% of neurologic complications.[57] Children with cancer are especially susceptible to seizures, which occur with a much higher incidence than in adults.[58] The causes of seizures among patients with cancer vary greatly and include primary brain tumors, brain metastases, metabolic derangements, and medications.[22] Drug-induced seizures are more common during intensive cancer chemotherapy that involves prolonged hospitalization, in patients with liver or kidney disease, and with high doses of antineoplastic agents, such as those recommended in protocols for bone marrow transplantation.

HERBAL MEDICINES AND TRADITIONAL CHINESE MEDICINE

Several herbal medicines and ingredients have been connected with drug-induced seizures. Actual incidences in humans are unknown due to poor mechanisms for detecting, reporting, and tracking adverse effects associated with these products.[59,60] Administration of typical doses of some of these substances has resulted in a seizure incidence of nearly 100% in animal models. Herbal products associated with seizures include nux vomica (strychnine), *Illicium henryi*, betel nut, *Morus alba* L. (mulberry), ephedra, eucalyptus, *Gingko biloba*, pennyroyal, sage, shankhapushpi, star anise, and star fruit.

STIMULANT DRUGS FOR ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Drugs such as methylphenidate and atomoxetine have been implicated as a cause of seizures in cases of overdose and abuse.[61,62] Early reports of seizures associated with drugs for attention deficit/hyperactivity disorder (ADHD) in children were complicated by the fact that this population is at increased risk for seizures. Two studies indicate that these drugs do not increase the risk of seizures in children with ADHD.[61,62] In one of these studies, children with epileptiform discharges on EEG were studied separately from those with normal EEG recordings.[61,62] Stimulant medications did not increase the risk of seizures in children with normal EEGs. A greater risk of seizures was reported in children with epileptiform discharges, but this could not be attributed to stimulant use. These data indicate that stimulant medications may be safely used in children with ADHD with little added risk of seizures.

MECHANISMS

Seizures are acute neurologic events resulting from hypersynchronous and hyperactive discharges of neurons. The precise mechanisms that result in this type of neuronal activity are poorly understood, in part because there are multiple causes of hypersynchronous activity. Proposed mechanisms of action of antiepileptic drugs involve excitatory neurotransmitters, ion channels (sodium, potassium, and calcium), and inhibitory neurotransmitters, providing limited understanding of the pathophysiology of seizures. However, other mechanisms are likely involved in the genesis of seizures due to toxicity and overdoses of medications.

Although specific mechanisms are not fully understood, there is some limited insight regarding potential mechanisms of seizures induced by some drugs. Proposed mechanisms by which specific drugs induce seizures are summarized in **Table 10-2**.[3,7,63-76] Meperidine is a well-documented causative agent in drug-induced seizures, most likely as a result of accumulation of the active metabolite normeperidine. The mechanism of seizures induced by penicillin and carbapenems is believed to be inhibition of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA). Seizures caused by theophylline overdose in children, adults, and the elderly may occur as a result of saturation of hepatic metabolism of the drug, resulting in progressive theophylline accumulation. Premature infants may be somewhat protected from theophylline-induced seizures because of the different metabolic pathways for theophylline in immature hepatic enzyme systems.[64]

Table 10-2 Mechanisms of Drug-Induced Seizures

Drug	Mechanism
5-fluorouracil[65]	Genetic polymorphism of dihydropyrimidine dehydrogenase leading to accumulation
Bupropion[66]	Increased noradrenergic activity
Carbapenems[49]	GABA antagonist; NMDA agonist
Cisplatin[67]	Hypomagnesemia, hypokalemia, hyponatremia
Clozapine[3]	Anticholinergic activity and reduced affinity for striatal dopaminergic receptors
Cyclosporine[68]	Direct neurotoxin
Fluoroquinolones[69]	Displacement of GABA from receptors
Tramadol[7]	Increased neuronal excitability
Interferon α[70]	Increased neuronal excitability
Isoniazid[71,72]	Disruption of pyridoxine metabolism
Maprotiline[73]	Increased noradrenergic activity

Meperidine[3]	Accumulation of metabolite, normeperidine, with CNS excitation activity
Methotrexate[74]	Mineralizing microangiopathy of cerebral vasculature
Penicillins[3]	GABA antagonist
Phenothiazines[75]	Dopamine antagonist activity
Theophylline[64]	Disruption of pyridoxine metabolism
Tricyclic antidepressants[76]	Increased noradrenergic activity

CNS = central nervous system, GABA = gamma-aminobutyric acid, NMDA = *N*-methyl-D-aspartic acid.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

A major problem with drug-induced seizures is accurate detection and diagnosis. The clinical presentation of seizures may be variable, ranging from decreased levels of consciousness to a major generalized tonic-clonic event (**Table 10-3**). Symptoms of a seizure can be extremely subtle, and unless caregivers are aware of the various presentations of seizures, these symptoms can be overlooked or misdiagnosed. In addition, seizures are usually brief and unpredictable events, complicating detection and diagnosis. Caregivers of individuals who are at increased risk for drug-induced seizures and who are receiving medications known to cause seizures should be trained regarding the typical symptoms of a seizure, including alteration of consciousness and uncontrolled muscle movement of part or all of the body.

Table 10-3 Signs and Symptoms Associated with Drug-Induced Seizures

- “Blacking out” spells, lapses in memory
- Sudden, unexplained alteration in consciousness
- Daydreaming
- Falling
- Shaking or convulsions of all limbs
- Jerks, shoulder shrugs
- Sudden episodes of various stereotypical sensations or automatic, uncontrolled movements

Seizures generally last for seconds to a couple of minutes, but drug-induced seizures can develop into status epilepticus, which requires immediate medical intervention. Patients with status epilepticus may not experience convulsions, but may present only with decreased levels of consciousness. When a patient experiences unexplained alterations in consciousness, seizures should be considered as a possible diagnosis.

Although the clinical presentation of a seizure is the primary method of detection, a definitive diagnosis is only possible with an EEG. Many other disorders are associated with clinical presentations that are similar to those of seizures (**Table 10-4**). The EEG should demonstrate abnormal neuronal activity that is consistent with a seizure. An EEG is preferably performed during a seizure to ensure that the abnormal activity is recorded, but the brief duration of most seizures makes this difficult to accomplish. Between seizures, the EEG can be completely normal, and is not helpful in determining whether the patient had a seizure. However, an abnormal EEG between seizures is indicative of an ongoing propensity for further seizures. The EEG should be performed by a skilled EEG technician and interpreted by a neurologist. It is particularly important to distinguish drug-induced seizures from seizures caused by neurological injuries or lesions, such as in patients with cancer, who may have brain metastases. Seizures that occur due to antineoplastic drug therapy may not be ongoing, and can often be treated or prevented by dose adjustments of chemotherapy agents. Criteria have been developed to assist in determining whether seizures are drug-induced or due to a different cause, and include development of encephalopathy and seizures soon after administration of a cancer chemotherapy agent, exclusion of metabolic and structural causes, and exclusion of seizures due to other drugs.[23,77]

Table 10-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Seizures

- Seizures due to other causes
- Anxiety or panic attack
- Cardiac arrhythmia
- Complicated migraine headache
- Hypoglycemia
- Psychogenic events
- Stroke
- Syncope
- Tics
- Transient ischemic attack

Beyond seizures associated with antineoplastic therapy, it is important to determine the risk for ongoing seizures, which would result in a diagnosis of epilepsy. Most drug-induced seizures are single events associated with the presence of the toxic agent. When therapy with the offending drug is discontinued, further seizures do not recur. However, if the patient experiences additional seizures after discontinuation of the causative drug with sufficient time for the drug to be eliminated, it is likely that epilepsy has developed and maintenance treatment should be initiated with an antiepileptic drug.

RISK FACTORS

Precise risk factors for drug-induced seizures have not been clearly identified. Possible risk factors for drug-induced seizures are listed in **Table 10-5**. Drugs known to cause seizures at therapeutic doses should be used with caution in patients with a history of epilepsy or seizures, or in patients with pre-existing neurological disorders involving the central nervous system. However, a history of epilepsy is not an absolute contraindication to therapy with drugs that may be associated with seizures, and treatment decisions should be made on an individual basis. Patients with compromised kidney or liver function are at risk for the accumulation of renally eliminated or hepatically metabolized drugs. For example, the risk of meperidine-induced seizures is increased sevenfold in patients with kidney disease.[3] In other patients, disorders or infections that compromise the blood–brain barrier may allow excessive penetration of a drug into the central nervous system and result in seizures. Finally, drugs known to cause metabolic disruptions such as hyponatremia or hypoglycemia could produce seizures, and serum sodium and/or glucose concentrations should be monitored carefully when using these drugs. Antiepileptic drugs can cause seizures when a drug is improperly chosen for management of a seizure or epilepsy syndrome. Juvenile myoclonic epilepsy is an example of an epilepsy syndrome that can be exacerbated by the use of the incorrect antiepileptic drug. Carbamazepine and oxcarbazepine have been shown to increase the risk of myoclonic and absence seizures in patients with juvenile myoclonic epilepsy.[18,19,22] Accurate diagnosis of seizure and proper selection of an antiepileptic drug therapy are essential to prevent worsening of seizures in this patient population. In addition, discontinuation of antiepileptic drugs can precipitate seizures, especially in patients with epilepsy. This typically occurs in association with abrupt discontinuation of an antiepileptic drug, but seizures can occur even during controlled withdrawal of therapy.[20,22] Withdrawal seizures have been reported in association with discontinuation of therapy with carbamazepine, oxcarbazepine, phenobarbital, phenytoin, felbamate, and benzodiazepines. Seizures resulting from the discontinuation of antiepileptic drugs can be severe and result in status epilepticus.

Table 10-5 Risk Factors for Drug-Induced Seizures

- History of epilepsy or seizures
- Cancer
- Compromised blood–brain barrier
- Pre-existing neurological disorders

- Concomitant use of central nervous system stimulant drugs
- Impaired metabolism of hepatically metabolized drugs in patients with liver disease
- Impaired elimination of renally eliminated drugs in patients with kidney disease

---

Seizures associated with antiepileptic drugs are most likely to occur with doses resulting in supratherapeutic serum concentrations. For example, serum phenytoin concentrations >30 mcg/mL have been associated with seizures.[78] Topiramate has also been reported to cause seizures at supratherapeutic doses.[79] In addition, drug-induced metabolic disturbances such as hyponatremia induced by carbamazepine or oxcarbazepine result in seizures.

Seizures associated with fluoroquinolones are relatively uncommon, and often occur in patients with a prior diagnosis of epilepsy, neurotrauma, or anoxia.[80] Some evidence exists that concomitant use of nonsteroidal anti-inflammatory agents increases the risk of fluoroquinolone-induced seizures. There appears to be a relationship between the chemical structure of the fluoroquinolone and the propensity to cause seizures. Compounds that contain the 7-piperazine or 7-pyrrolidine moieties (e.g., ciprofloxacin, enoxacin, norfloxacin, tosufloxacin, clinafloxacin) have an increased potential to cause seizures.[81] The majority of reported cases of carbapenem-induced seizures have occurred in patients with kidney disease or a compromised blood–brain barrier, allowing greater penetration of the drug into the brain.

Theophylline-induced seizures can occur at any dose. Older children, adults, and the elderly are particularly vulnerable to seizures associated with theophylline, especially in overdose. In one case series, seizures related to theophylline developed in 6% of elderly patients.[82]

MORBIDITY AND MORTALITY

Drug-induced seizures are typically single events of short duration that are associated with a low risk of morbidity or mortality. However, during these events, an individual may experience an injury, such as lacerations or broken bones from falling, or may injure others if the seizure occurs while driving a motor vehicle or operating equipment or machinery. It is unlikely that typical drug-induced seizures result in repeated seizures, as may occur in patients with epilepsy.

Status epilepticus occurs rarely as a result of drug-induced seizures, but is associated with increased morbidity and mortality. Uncontrolled, prolonged seizures can result in permanent neurologic damage and increase the risk of ongoing seizures. Additionally, uncontrolled status epilepticus can result in death.

PREVENTION

As the mechanisms and causes of drug-induced seizures are diverse, it is difficult to describe specific plans for prevention (**Table 10-6**). Caution should be exercised when using medications known to cause seizures in patients with a history of epilepsy or seizures. Efforts should be made to ensure proper dose adjustments of drugs in patients with kidney or liver disease. Increased monitoring of metabolic function parameters may be helpful in preventing seizures due to drug effects on serum chemistry and homeostasis. Premedication and combination anesthesia may reduce the risk of seizures associated with sevoflurane. To minimize the risk of seizures, pretreatment with benzodiazepines and/or narcotics and concomitant use of nitrous oxide have been suggested.[83] In addition, hypocapnia should be avoided and a maximum of 1.5 minimum alveolar concentration of sevoflurane should be used during anesthesia to prevent sevoflurane-induced seizures.

Table 10-6 Approaches to Help Prevent Drug-Induced Seizures

- Appropriate dose adjustment of potentially seizure-inducing drugs in patients with liver or kidney disease
- Appropriate monitoring of laboratory values (e.g., serum electrolytes, kidney function, liver function, serum glucose concentrations)
- Avoid concomitant use of drugs that are central nervous system stimulants
- Avoid abrupt discontinuation of therapy with drugs with central nervous system activity

To reduce the risk of withdrawal seizures, therapy with antiepileptic drugs should be withdrawn over 1–2 months, unless potentially life-threatening adverse effects are occurring, in which case more rapid discontinuation of therapy is warranted. Care should be taken to ensure proper doses and laboratory monitoring of antiepileptic drug therapy, including serum antiepileptic drug concentrations, serum electrolyte concentrations, and kidney and liver function tests.

Appropriate dose adjustment of penicillins and carbapenems in patients with kidney disease or a compromised blood–brain barrier is the best method of preventing seizures associated with these agents. These drugs and fluoroquinolone antibiotics should be used with caution in patients with a history of seizures. Similarly, other drugs, such as hydroxychloroquine and antipsychotic agents should be used with caution in patients with a history of epilepsy.[84,85] Some have suggested initiating therapy with an antiepileptic drug in patients in whom therapy with clozapine is initiated in an attempt to prevent seizures.[28]

Many of the reported cases of seizures associated with ephedra or ma huang occurred in patients without a history of epilepsy, and often occurred with the coadministration of other stimulant drugs, like phenylpropanolamine or caffeine.[34]

Clearly, other stimulant drugs should not be administered in combination with ephedra.

MANAGEMENT

Because drug-induced seizures can occur through a variety of mechanisms, treatment strategies should be approached carefully and should be individualized. The first step is to immediately discontinue the causative agent, or in the case of withdrawal seizures, to reinitiate therapy with the discontinued medication. If the risk of a second acute seizure appears to be low, then pharmacologic interventions to treat seizures are probably not necessary. However, if the risk of another acute seizure is high, then seizures should be treated aggressively. The focus of treatment is prevention of additional acute seizures.

Some drugs induce seizures by altering metabolism leading to disorders such as hypoglycemia or hyponatremia. In these cases, the underlying metabolic abnormality should be identified and corrected before the initiation of therapy with drugs commonly used to treat seizures. Antiepileptic drugs are associated with numerous adverse drug reactions, and indiscriminate use should be avoided.

Management of drug-induced seizures is dependent on the causative agent. However, a general treatment approach to seizures can be used.[86] The key to treatment and prevention of additional seizures is rapid identification of the causative agent and rapid implementation of an appropriate treatment plan. When the likelihood of repeated acute seizures is low, more time is available to discontinue the offending agent or take alternative actions.

The acute treatment of seizures typically involves provision of supportive care followed by drug therapy to control the seizures. Usually a benzodiazepine such as lorazepam, diazepam, or midazolam is administered to provide rapid control of seizures. Most patients respond to these measures. If seizures are not controlled or recur, administration of a benzodiazepine can be repeated or therapy with an antiepileptic drug can be initiated. New evidence suggests that phenytoin should be avoided when treating drug-induced seizures.[86] In the very rare situations in which patients do not respond to additional doses of a benzodiazepine, other agents such as short-acting barbiturates, general anesthetics, exceptionally high doses of a benzodiazepine, or other antiepileptic drugs may be used.

Benzodiazepines are usually effective in treating and preventing carbapenem-induced seizures, because benzodiazepines enhance GABA activity.[87] For patients with seizures induced by tricyclic antidepressants, benzodiazepines are the preferred drugs for treatment.[17] In this situation, phenytoin should be avoided, because of its lack of efficacy and the possibility of enhancing the arrhythmogenic effects of tricyclics. Benzodiazepines are recommended for the management of seizures induced by antimalarial drugs.[88] However, benzodiazepines may not be as effective for the management of theophylline-induced seizures.[89] Theophylline may antagonize the effects of benzodiazepines, rendering them less effective. Therefore, barbiturates are the preferred agents for treating theophylline-induced seizures. Loading doses of phenobarbital or pentobarbital, 5–15 mg/kg, should be administered, with additional loading doses given until seizures terminate.[90] Patients should be intubated and mechanically ventilated prior to initiation of intravenous doses of barbiturates because of the respiratory and cardiovascular adverse effects of these agents.

If it is determined that seizures are induced by an antineoplastic agent, the general recommendation is not to treat the seizures, when possible, but to adjust the cancer chemotherapy doses and regimen.[22] Care should also be taken to address underlying metabolic changes associated with antineoplastic drugs that can result in seizures. However, if there are other potential causes of the seizures, especially central nervous system tumors, ongoing use of antiepileptic therapy is indicated.

INFORMATION FOR PATIENTS

As drug-induced seizures are rare events and are usually very short in duration, education of all patients regarding the seizure risk when receiving potentially seizure-inducing drugs may not be productive. Individuals who are at increased risk for seizures should be advised regarding signs and symptoms. Caregivers should be instructed concerning first aid for seizures. If a seizure occurs, caregivers should protect the patient from self-injury or injuring others by laying the person on his or her side, placing a pillow under the head, making sure the airway remains clear, and helping the individual become reoriented once the seizure subsides. In addition, timing the duration of the seizure with a clock is important, and emergency medical care should be called if a seizure lasts longer than 5 minutes or when a seizure occurs in an individual without a history of seizures. Forcing objects into the patient's mouth or restraining the patient should never be attempted. In addition to instruction on managing seizures, individuals with a history of epilepsy should be advised to avoid medications that may cause seizures, particularly nonprescription drugs and herbal products, and to avoid abrupt discontinuation of antiepileptic agents.

CHAPTER 11

Stroke

Denise H. Rhoney

Stroke, the fifth leading cause of death in the United States, refers to a sudden onset of focal neurologic deficit.[1,2] There are two main types of stroke: ischemic and hemorrhagic. Drugs should always be considered as a possible etiology of either type of stroke. A secondary cause of drug-induced stroke could be associated with medications that induce other diseases discussed elsewhere in this text that are also risk factors for stroke, such as hypertension, hyperlidemia, or atrial fibrillation.

ISCHEMIC STROKE

CAUSATIVE AGENTS

Drugs that have been reported to cause ischemic stroke are listed in **Table 11-1**.[3-53] Many of the agents listed in the table have been associated with both ischemic and hemorrhagic stroke. For many medications, the potential association with drug-induced stroke is controversial.

There is substantial controversy as to whether oral contraceptives are a cause of stroke. Many studies have attempted to assess the possible relationship between oral contraceptives and stroke, but the results are contradictory. Higher-dose formulations have been shown to increase the risk of stroke in specific subgroups of patients: smokers; those with hypertension; age >35 years; prior history of stroke; those with hyperlipidemia; and those with a history of migraine headaches. Although the potential increased risk of stroke appears to be diminished with lower-dose formulations of oral contraceptives, meta-analyses have reported conflicting results.[54,55] Therefore, oral contraceptives should be used with caution in women at risk for stroke.[56-58] The rate of ischemic stroke among users of the norelgestromin/ethinyl estradiol (Ortho EVRA) contraceptive patch is 13.6/100,000 woman–years, which is similar to the stroke rate in users of norgestimate-containing oral contraceptives (11.3/1000,000 woman–years).[59]

Data from postmenopausal women receiving hormone replacement therapy with estrogen provide some additional information regarding the risk of stroke in patients receiving oral contraceptives. In the Women's Health Initiative, a randomized trial of 16,500 generally healthy postmenopausal women, the combination of estrogen and progestin increased the relative risk of ischemic stroke by 44%.[60] Although patients in this trial were relatively healthy, they were substantially older than typical patients receiving therapy with oral contraceptives; therefore, it may not be appropriate to draw inferences from these results regarding the risk of stroke associated with oral contraceptive therapy in younger patients.

Table 11-1 Agents Implicated in Drug-Induced Ischemic Stroke

Agent	Incidence	Level of Evidence[a]
Alcohol abuse (≥5 drinks daily)[3,4]	RR 1.69, 95% CI 1.34–2.15	B
Amphetamines[5-7]	NK	C
Cisplatin[8-15]	0.137%	B
Cocaine[6,16-23]	NK	B
Ecstasy[6,24]	NK	C
Haloperidol[25]	6.43 per 1,000 person-years	B
Heroin[4,6,26]	NK	C
Hormone replacement in postmenopausal women[27]	RR 1.31, 95% CI 1.02–1.68	A
Intranasal phenoxazoline or oxymetazoline[28]	NK	C
Intravenous immunoglobulin[29]	NK	C
	NK	C

Isometheptene mucate[30]		
Marijuana[4,31]	NK	C
Methylphenidate[6]	NK	C
Nicotine[4,32,33]	25% RR 1.8, 95% CI 1.3–3.6	A
Nonsteroidal anti-inflammatory agents[34-36]	NK	B
Olanzapine[37-39,b]	NK	C
Oral contraceptives (women age 25–44 years >50 mcg estradiol)[40,41]	0.9–10/100,000 RR 2.8, 95% CI 1.2–4.4	B
Prothrombin complex concentrate[42-44]	1.9%	A
Recombinant factor VIIa[45]	NK[b]	B
Risperidone[25,37,38,c]	2.88 per 1,000 person-years	B
Selective serotonin reuptake inhibitors[46-50,d]	OR 1.48, 95% CI 1.08–2.02	B
Serotonin–norepinephrine reuptake inhibitors[48,d]	NK	B
Sumatriptan[3,51]	NK	C
Tamoxifen[52,53]	RR 1.49, 95% CI 1.16–1.90	B

CI = confidence interval, NK = not known, OR = odds ratio, RR = relative risk.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Primarily reported in patients with dementia; total of 39 cases reported.

[c] A total of 151 thromboembolic events reported with rFVIIa in Food and Drug Administration Adverse Event Reporting System.

[d] Primarily reported with high doses.

In December 2004, the U.S. Food and Drug Administration (FDA) issued a health advisory concerning the use of nonsteroidal anti-inflammatory agents (NSAIDs) and cyclooxygenase (COX)-2 selective drugs.[36] There is evidence that these agents increase the risk for myocardial infarction and stroke when used for extended periods of time or in high-risk settings (such as immediately after cardiac surgery).[34] In 2004 and 2005, respectively, rofecoxib and valdecoxib were withdrawn from the U.S. market. A National Institutes of Health (NIH) clinical trial with celecoxib was suspended due to increased cardiovascular events, but the drug was not removed from the market. However, the FDA recommends the use of other agents or the lowest effective dose and required the addition of a "black box" warning to the labeling. Additionally, the NIH halted an Alzheimer disease trial that showed an increase in the risk of cardiovascular events in patients receiving naproxen but not celecoxib.[35] Recently the extended follow-up data from the Adenomatous Polyp PRevention On Vioxx study found an increased risk of ischemic stroke associated with rofecoxib compared to placebo and reported that 7 of the 18 ischemic strokes occurred after rofecoxib therapy had been discontinued.[34] This finding raises concern regarding the risk of stroke in patients who have a previous exposure to rofecoxib. The FDA-issued public health advisory is as follows[36]:

1. Physicians prescribing COX-2 selective agents should consider this emerging information when weighing the benefits against risks for individual patients. Patients who are at a high risk of gastrointestinal bleeding, have a history of intolerance to nonselective NSAIDs, or are not doing well on nonselective NSAIDs may be appropriate candidates for COX-2 selective agents.
2. Individual patient risk for cardiovascular events and other risks commonly associated with NSAIDs should be taken into account for each prescribing situation.
3. Consumers are advised that all nonprescription pain medications, including NSAIDs, should be used in strict accordance with the label directions. If an NSAID is needed for longer than 10 days, a physician should be consulted.

The American Heart Association (AHA) has recommended a stepped-care approach for the management of musculoskeletal symptoms in patients with risk factors or known cardiovascular disease.[35,61]

EPIDEMIOLOGY

The most common type of nondrug-induced stroke is ischemic, which accounts for 85% of all cases. Of ischemic strokes, 65% are atherothrombotic with the remainder cardioembolic in origin. The overall incidence of drug-induced stroke is unknown, but generally considered to be low. In young adults (<50 years of age) drug-related etiologies can be identified in 15–38% of ischemic strokes.[6,62] Illicit drug use, particularly cocaine, is commonly implicated in younger patients who lack other known vascular risk factors. Since the emergence of the more potent alkaloidal cocaine ("crack"), there has been a significant increase in the number of case reports of cocaine-associated stroke.[63] The incidence of all drug-induced strokes may be on the rise.[6] The incidence of stroke associated with specific agents is presented in Table 11-1.

MECHANISMS

There are many proposed mechanisms for drug-induced strokes. Mechanisms by which drugs result in stroke may be multifactorial and are discussed below and presented in **Table 11-2**.

Table 11-2 Mechanisms of Drug-Induced Ischemic Stroke

Drug	Mechanism(s)
Intravenous drugs of abuse (e.g., heroin) Cocaine Methylphenidate (from injection of oral product) Tamoxifen	Cerebral embolism
Cocaine Amphetamines Methylphenidate Sumatriptan SSRI SNRI	Vasoconstriction/vasospasm
Amphetamines Cocaine Alcohol Caffeine Cigarette smoking	Acute hypertension
Heroin Cocaine Amphetamines	Vasculitis
Cocaine Cigarette smoking Nonsteroidal anti-inflammatory agents Cisplatin	Induces direct vascular damage and subsequently promotes platelet aggregation and vasoconstriction
Olanzapine Risperidone	Orthostatic hypotension

SSRI = selective serotonin reuptake inhibitor, SNRI = serotonin norepinephrine reuptake inhibitor.

EMBOLIC MECHANISMS

Embolism can produce a stroke when a clot, plaque, platelet aggregate, or foreign body breaks off into the circulation and obstructs a cerebral artery. Intravenous drugs of abuse (i.e., heroin) can be associated with cerebral infarction due to embolic vessel occlusion, infective endocarditis, or hemorrhage due to rupture of a septic (mycotic) aneurysm. Stroke is a complication in about 20% of patients with infective endocarditis. Cocaine and other drugs may cause heart disease, which results in release of emboli to the brain. Foreign body emboli, primarily from talc fillers, have been reported after injection of agents intended for oral administration (i.e., methylphenidate).[64] Foreign substances injected into the systemic circulation may embed in the lung, resulting in granulomatous reactions that ultimately provide a path for this foreign material to reach the brain. Tamoxifen may be associated with a paradoxical embolism and subsequent cerebral venous thrombosis.[53]

VASOCONSTRICTION/VASOSPASM

Systemic vasoconstriction can lead to hypertension and intracerebral hemorrhage (ICH), whereas cerebral vasoconstriction can lead to infarction. Vasoconstriction may be transient or prolonged. Vasospasm with subsequent cerebral infarction may occur in association with cocaine, amphetamines, phenylpropanolamine, ephedrine, and methylphenidate.[65] Cocaine temporarily causes vasoconstriction, thus reducing blood supply to various brain regions. Cocaine may potentiate the effects of serotonin by blocking its reuptake, resulting in vasoconstriction.[66] In addition, cocaine exerts direct effects on calcium channels leading to release of intracellular calcium in cerebral vascular smooth muscle cells.[63] Other possible mechanisms of cocaine-induced vasospasm are via endothelin-1 release and reuptake of dopamine at presynaptic nerve terminals. There appears to be a cumulative effect of cocaine exposure and the risk of stroke.[63] The use of selective serotonin reuptake inhibitors and serotonin-norepinephrine reuptake inhibitors can cause vasoconstrictive stroke (Call–Fleming syndrome) or vasospasm.[46,47] Underlying atherosclerosis may augment this vasoconstriction. Sumatriptan binds to a particular subpopulation of 5-hydroxytryptamine (5-HT$_1$) receptors in the pia and dural vessels, leading to vasconstriction.[67] Subcutaneous administration of sumatriptan has been shown to result in vasoconstriction of the middle cerebral and internal carotid arteries within 30 minutes.[68] There have been case reports of stroke associated with triptan use; however, patients with migraine are also at increased risk of stroke.[69]

ACUTE HYPERTENSION

The primary mechanism of hypertension-associated drug-induced stroke is drug effects on neurotransmitters. Many drugs increase catecholamine release from central noradrenergic nerve terminals (i.e., amphetamines, ephedra, nonprescription sympathomimetics), block reuptake of catecholamines into adrenergic nerve terminals (i.e., cocaine), or increase plasma catecholamine concentrations (i.e., ethanol, cocaine). Hypertension related to drug use may disrupt cerebral autoregulation, promote reperfusion of brain tissue, or damage cerebral arterioles leading to hemorrhage. Cigarette smoking acutely elevates blood pressure and reduces cerebral blood flow.[70-72] Alcohol acutely and chronically increases blood pressure related to increased adrenergic activity and increased plasma concentrations of cortisol, renin, aldosterone, and vasopressin.[73-75]

VASCULITIS

Inflammation of small-, medium-, and large-size intracranial arteries and subsequent development of arteritis is a reported mechanism of stroke induced by drugs such as heroin, amphetamines, cocaine, ephedra, and pseudoephedrine.[76] These agents are associated with an inflammatory vasculopathy and vessel wall necrosis.[77]

CLOTTING DERANGEMENTS

Platelets play an important role in the development of thrombosis. With endothelial damage, vessel collagen can be exposed to blood, and acts as a triggering mechanism for platelet activation, resulting in release of adenosine diphosphate from the platelets, causing platelets to aggregate. Thromboxane A_2 is produced, which also promotes platelet aggregation and vasoconstriction. Cocaine may stimulate platelet aggregation and inhibit prostacyclin.[78] Cigarette smoking aggravates atherosclerosis and increases arterial wall stiffness, ultimately increasing the likelihood of plaque formation. Smoking increases platelet reactivity and inhibits prostacyclin formation.[79] Alcohol consumption may elevate blood pressure and interfere with platelet function; chronic use may result in coagulation abnormalities due to liver impairment. Nonsteroidal anti-inflammatory agents act primarily via inhibition of COX, which consists of 2 major isoenzymes (COX-1 and COX-2). Experimental evidence suggests that inhibition of COX-2 results in a shift in the prothrombotic/antithorombotic balance toward thrombosis. The differential biological effects of these agents are a result of the degree of selectivity for COX-2 versus COX-1.[35] Cisplatin induces direct endovascular damage and also indirect damage via free radical-induced lipid peroxidation. An increase in plasma concentrations of von Willebrand factor has been reported during cisplatin chemotherapy regimens and is evidence of direct endovascular damage leading to platelet aggregation and vasoconstriction.[80] In addition, cisplatin may reduce activity of the anticoagulant protein C.[13]

ORTHOSTATIC HYPOTENSION

A potential mechanism for stroke associated with atypical antipsychotic agents is orthostatic hypotension leading to “watershed” strokes. Hyperprolactinemia induced by these drugs may also result in promotion of platelet aggregation.[81]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Clinically, it is difficult to distinguish drug-induced stroke from nondrug-induced etiologies. The diagnosis of drug-induced stroke is often made by exclusion of other causes, or through serum or urine drug testing. The typical patient experiencing a stroke presents with an abrupt onset of neurologic deficits, which can include hemiparesis, speech disturbance, hemisensory loss, monocular or visual field loss, and/or ataxia. The clinical presentation of both ischemic stroke and ICH is dependent on the anatomical location of the infarction. It is not possible to distinguish an ischemic stroke from ICH based on clinical examination alone, although several characteristics are more indicative of ICH, including headache, impaired level of consciousness, nausea and vomiting, and extreme elevations of blood pressure. Subarachnoid hemorrhage must be suspected in a patient who experiences a sudden new severe headache. Drug-induced stroke can occur at any time during therapy with a potentially causative agent. Common signs and symptoms of drug-induced ischemic stroke are presented in Table 11-3.

Table 11-3 Signs and Symptoms Associated with Drug-Induced Ischemic Stroke

Signs	Symptoms
Anterior cerebral artery occlusion	Contralateral hemiparesis Confusion Gait apraxia
Middle cerebral artery blockage	Contralateral hemiparesis Dysarthria Hemianesthesia Contralateral homonymous hemianopia Aphasia Apraxia Sensory neglect
Posterior cerebral artery blockage	Contralateral homonymous hemianopia Unilateral cortical blindness Memory loss Unilateral 3rd cranial nerve palsy
Ophthalmic artery blockage	Monocular loss of vision
Vertebrobasilar system blockage	Unilateral or bilateral cranial nerve deficits (e.g. nystagmus, vertigo, dysphagia, dysarthria, diplopia, blindness) Ataxia Impaired consciousness

Drug-induced stroke must be distinguished from stroke due to other etiologies. Conditions to consider in the differential diagnosis of drug-induced stroke are presented in **Table 11-4**. It is difficult to distinguish between drug-induced and nondrug-induced causes of stroke unless symptoms are temporally related to the ingestion of substances of abuse or agents with surrogate monitoring parameters (i.e., drug screen) that can quantitatively be assessed.

Table 11-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Ischemic Stroke

- Brain tumor
- Cerebral abscess
- Cerebral hemorrhage
- Cranial trauma
- Encephalitis
- Malingering/somatization
- Meningitis
- Metabolic encephalopathy (hypoglycemia, diabetic ketoacidosis, hyperosmolar coma, hepatic encephalopathy, renal failure, hypercapnia, sepsis)
- Migraine headache
- Peripheral neuropathy
- Postcardiac arrest ischemia
- Psychiatric symptoms
- Seizure disorder (with postictal paralysis)
- Syncope

Diagnosis of stroke consists of a thorough evaluation of patient history, clinical examination, laboratory evaluation, and imaging studies, including computerized tomography (CT) scan, cerebral angiography, and magnetic resonance imaging (MRI). Laboratory studies should consist of serum electrolyte and glucose concentrations, complete blood count, coagulation parameters, and drug screen evaluation. A CT scan is essential to differentiate between ischemic and hemorrhagic stroke.

RISK FACTORS

Risk factors for drug-induced stroke are presented in **Table 11-5**. An underlying history of hypertension is one of the most common risk factors. In addition, any patient with other risk factors for stroke is at a higher risk for drug-induced stroke. The Framingham study identified five factors that placed the general population at increased risk of ischemic stroke: elevated systolic blood pressure, elevated serum cholesterol concentration, glucose intolerance, cigarette smoking, and left ventricular hypertrophy by electrocardiogram.[82] Risk factors for ischemic stroke have been outlined in recent guidelines from the American Stroke Association/AHA.[83]

Table 11-5 Risk Factors for Drug-Induced Ischemic Stroke[83]

- Concurrent caffeine use
- Concurrent tobacco use
- Dementia
- Diabetes
- Elderly
- Exposure to drugs of abuse
- High doses of potentially causative agents
- History of vascular events
- Hypertension
- Migraine headaches with aura
- Physical inactivity
- Polydrug use
- Pregnancy
- Previous stroke

MORBIDITY AND MORTALITY

Stroke is one of the most devastating diseases, yet one of the most preventable. The overall direct and indirect economic impact of stroke is approximately $40.9 billion annually.[84] Stroke is the fifth leading cause of death in the United States and a leading cause of disability in hospitalized patients.[1,2] Long-term sequelae of a stroke, whether induced by drugs or other etiologies, include: memory loss, depression, behavioral changes, emotional lability, difficulty performing activities of daily living, communication problems, paralysis, and neglect on the side of the body corresponding to the location of the stroke.

PREVENTION

The most effective means of prevention of drug-induced stroke is avoidance of agents known to be associated with stroke, especially in high-risk patients. Strategies for prevention of drug-induced stroke are listed in **Table 11-6**.[83] Drug-induced stroke may also be prevented by minimizing other risk factors for ischemic stroke (e.g., hypertension, hyperlipidemia, smoking, diabetes). However, the mainstay of prevention is patient education and identification of risk factors, particularly in those patients that are at high risk.

Table 11-6 Approaches to Help Prevent Drug-Induced Ischemic Stroke[83]

Drug	Condition	Prevention
Alcohol	Moderation	Men should consume no more than 2 drinks/day and nonpregnant women should consume no more than 1 drink/day Control hypertension
All drugs	General risk factor reduction	Control of hypertension Glucose control Cholesterol-lowering therapy Weight management Atrial fibrillation management Sleep apnea management Physical activity Discontinue drugs known to be associated with stroke in patients at high risk
Cigarette smoking	Smoking cessation	Encourage patient and family to stop smoking Provide counseling, nicotine replacement and formal programs
Drug abuse	Cessation	Rehabilitation program
Hormone replacement therapy	Avoid use for primary prevention of stroke	If used for other indications the patient should be informed of vascular risks
NSAID	Musculoskeletal pain	Refer to scientific statement for stepped care approach recommendations[50]
Oral contraceptive use	Avoid in those at high risk	Inform patients about stroke risk and encourage alternative forms of birth control among women who smoke cigarettes, have migraines (especially with older age or smoking), are >35 years of age, or have had prior thromboembolic events
SSRI/SNRI	Possibly dose-related	Use lowest effective dose for all indications

NSAID = nonsteroidal anti-inflammatory drug, SNRI = serotonin norepinephrine reuptake inhibitor, SSRI = selective serotonin reuptake inhibitor.

MANAGEMENT

The management of any stroke patient includes many phases: prevention of stroke or other vascular disease; supportive and medical management during the acute phase; measures to mitigate the ongoing pathologic process; and rehabilitation. In addition, discontinuation of the offending agent (if identified) is essential.

Approaches to treatment of drug-induced acute ischemic stroke are similar to those of stroke due to other etiologies (please refer to treatment guidelines published for the acute management of ischemic stroke).[85] Hospital admission is indicated for any patient presenting with an acute stroke. Neurologic progression and cardiac sequelae are common in the early stages of a stroke. Preventing and recognizing secondary complications such as aspiration pneumonia and pulmonary embolism are essential. The only proven specific treatment for acute ischemic stroke at present is the thrombolytic agent recombinant tissue plasminogen activator (rt-PA). In appropriately selected patients, rt-PA significantly increases the likelihood of a good neurologic recovery.[86,87] To be eligible for rt-PA therapy, patients should have a well-described time of symptom onset within 4.5 hours of initiation of rt-PA treatment. Every effort should be made to shorten any delays in the initiation of treatment, because earlier treatment is associated with increased outcome benefits. The dose of rt-PA for stroke is 0.9 mg/kg intravenously over 1 hour, 10% as an initial bolus. The maximum total dose is 90 mg. During the first 24 hours after treatment, therapy with antithrombotic agents such as heparin and aspirin should be withheld, blood pressure should be strictly maintained at <180/105 mm Hg, and close neurologic and cardiac monitoring should be performed in an intensive care unit or stroke unit.[85]

The new guidelines also include recommendations for endovascular interventions including mechanical thrombectomy and intra-arterial thrombolysis.[85] If a patient meets criteria for undergoing endovascular therapy, this should be considered in addition to receiving rt-PA, and the patient should be transferred to a comprehensive stroke center. The guidelines recommend that patients should undergo endovascular therapy with a stent retriever if they meet the following criteria: prestroke modified Rankin score of 0 to 1; acute ischemic stroke with receipt of intravenous rt-PA within 4.5 hours of symptom onset; causative occlusion of the internal carotid artery or proximal (M1) middle cerebral artery; age 18 years or older; NIH Stroke Scale (NIHSS) score of 6 or greater; Alberta Stroke Program Early CT score of 6 or greater; and treatment that can be initiated (groin puncture) within 6 hours of symptom onset.[85] Other recommendations suggest that intra-arterial rt-PA could be administered in carefully selected patients who have contraindications to the use of intravenous rt-PA and that endovascular approaches may be reasonable in patients who do not meet the criteria listed above.[85]

Fever (temperature >38°C) and glucose disorders should be treated aggressively in patients with acute stroke because both conditions exacerbate cerebral ischemia and may worsen neurologic outcome.[88] A twofold increase in short-term mortality has been reported in patients with hyperthermia within the first 24 hours of hospitalization with acute stroke.[88] Persistent in-hospital hyperglycemia during the first 24 hours is associated with worse outcomes when compared to normoglycemia; therefore, hyperglycemia treatment to achieve a target blood glucose range of 140–180 mg/dL is recommended. Additionally, hypoglycemia (blood glucose <60 mg/dL) should be treated.[85]

Arterial blood pressure is a dynamic parameter that may fluctuate substantially and is associated with clinical consequences. Studies have found a U-shaped relationship between admission blood pressure and favorable clinical outcomes, with optimal systolic and diastolic blood pressure ranges of 121–200 mm Hg and 81–110 mm Hg, respectively.[89] In-hospital elevations in blood pressure immediately following acute stroke have shown an inverse relationship to outcome; that is, increased blood pressure is associated with worse outcomes.[90,91] The appropriateness of treating acute hypertension in patients who do not qualify for reperfusion therapies is challenging. In fact, lowering blood pressure excessively may exacerbate cerebral ischemia in patients experiencing stroke. In many patients, blood pressure spontaneously decreases during the first 24 hours following a stroke. The most recent guidelines recommend, for patients not receiving reperfusion therapies, withholding of antihypertensive therapy unless the systolic pressure is >220 mm Hg or the diastolic pressure is >120 mm Hg. If antihypertensive therapy is initiated in patients who exceed these thresholds, then it is reasonable to lower blood pressure by 15% from baseline during the first 24 hours.[85]

If antihypertensive therapy is needed in the acute stage of drug-induced stroke, intravenous agents should be used, particularly those for which doses can be easily titrated. Labetalol may be administered initially as intravenous boluses of 10–20 mg until the desired blood pressure is achieved. Labetalol should be avoided in patients with contraindications to β-blockers. Nicardipine therapy may be initiated as a continuous intravenous infusion of 5 mg/hr, and the infusion rate can be adjusted to achieve the desired blood pressure. Other agents may also be useful depending on the clinical situation.[85]

After the acute phase of a drug-induced stroke, risk factor management is essential.[92] The appropriate specific preventive agent may be aspirin, clopidogrel, combination aspirin/extended-release dipyridamole, or an oral anticoagulant. Of these, aspirin is the most frequently prescribed for thrombotic causes of stroke. There is a lack of consensus regarding the optimal dose for stroke prevention. Doses of 50–325 mg have been shown to be effective. For patients with cardioembolic sources of stroke including atrial fibrillation, oral anticoagulation is recommended. For those with nonvalvular atrial fibrillation the guidelines currently recommend warfarin, apixaban, dabigatran, or rivaroxaban as reasonable options. Dose selection of these newer target-specific oral anticoagulants should be performed with careful attention to kidney function and drug interactions. Warfarin is indicated for patients with atrial fibrillation associated with valvular disease. The standard target range for the international normalized ratio (INR) is 2–3, however, patients with mechanical prosthetic valves may require a higher INR (2.5–3.5), but this places them at increased risk for ICH. In addition, any other risk factor that may be present (e.g., hyperlipidemia, hypertension, diabetes) should be managed aggressively. Please refer to secondary prevention guidelines for specific recommendations.[92]

INFORMATION FOR PATIENTS

Risk factor assessment is essential for prevention of drug-induced stroke. Because patients do not obtain many of the drugs known to cause stroke at pharmacies, it is extremely important that patients at risk are counseled to consult healthcare professionals before purchasing nonprescription drugs. For example, patients with hypertension should be advised that cough and cold medicines or herbal products might contain sympathomimetic drugs that could place them at increased risk for drug-induced stroke. Patients should be instructed to inform their healthcare professionals of all medications that they are taking, to facilitate a full evaluation of potential agents that may be associated with drug-induced stroke. Because medications that may induce stroke include a large number of recreational drugs of abuse, appropriate counseling regarding risks associated with these agents should be performed and referral to rehabilitation programs should be considered. In addition, all patients should be counseled regarding the signs and symptoms of and risk factors for drug-induced ischemic stroke and should be instructed to seek medical attention at the onset of symptoms.

INTRACEREBRAL HEMORRHAGE

CAUSATIVE AGENTS

ICH describes bleeding into the brain parenchyma with possible extension into the ventricular system or subarachnoid space. This chapter will focus on ICH, although studies provide information for hemorrhagic stroke, which includes ICH and subarachnoid hemorrhage; therefore, the term *hemorrhagic stroke* will be used when applicable. Drugs that have been reported to cause hemorrhagic stroke are listed in **Table 11-7**.[4,6,16,20,26,47,50,86,87,93-162] Many of the agents that are associated with ICH are used as therapeutic agents for other disease states. Symptomatic ICH is one of the most feared complications associated with the use of rt-PA for ischemic stroke and occurs in approximately 6% of treated patients. It is estimated that for every 100 patients treated with rt-PA, one will experience severe disability or death associated with symptomatic ICH.[163] Most patients who experience this devastating complication have more severe baseline infarcts.[163-165] Other risk factors for symptomatic ICH associated with rt-PA will be discussed later in the chapter (i.e., Table 11-11).

Vitamin K antagonists (warfarin) have been the standard of care for the treatment of thromboembolic diseases for many years. Target-specific oral anticoagulants (dabigatran, rivaroxaban, apixaban, edoxaban) have been developed and found to be at least noninferior to warfarin (target INR 2–3). The rate of major bleeding among long-term users of warfarin is 1.5–5.2% per year with a mortality rate from major bleeding that exceeds 13%.[166,167] Intracranial bleeding is the most feared complication and accounts for 8.7% of the major bleeding episodes with a 46–55% mortality rate.[168,169] A recent meta-analysis compared the risk of bleeding associated with target specific oral anticoagulants with that of warfarin in patients with atrial fibrillation and venous thromboembolism.[170] The results indicate that the use of target-specific oral anticoagulants is associated with significant reductions in the risk of major bleeding (RR 0.72, 95% CI 0.62–0.85, NNT 156), fatal bleeding (RR 0.53, 95% CI 0.43–0.64, NNT 454), intracranial bleeding (RR 0.43, 95% CI 0.37–0.50, NNT 185), clinically relevant bleeding (RR 0.78, 95% CI 0.68–0.90, NNT 99), and total bleeding (RR 0.76, 95% CI 0.71–0.82, NNT 18). Data from the clinical trials also suggest that the rates of major bleeding associated with these newer agents are 2–3% per year, and rates of hemorrhagic stroke are 0.1–0.5% per year.[106,171-175]

Table 11-7 Agents Implicated in Drug-Induced Intracerebral Hemorrhage

Agent	Incidence	Level of Evidence[a]
Abciximab[93,94]	5.5%	B
Amphetamines[95-97]	NK	C
Apixaban[98]	0.33%/yr	A
Aspirin[99,100]	12/10,000	A
Aspirin + clopidogrel[101]	0.4%/yr	A
Cocaine[4,6,16,20,102-104]	NK	B
Dabigatran[105,106]	150 mg = 0.31%/yr 110 mg = 0.23%/yr	A
Edoxaban[107]	0.26%/yr	A
Ephedra-containing products (32 mg/day)[108-111,b]	NK	B
Glycoprotein IIb/IIIa inhibitors[111-114] With heparin Without heparin	0.12% 0.07%	B
Heparin[115-117]	0.3%	A
Heavy alcohol use (>60 g/day or >3 drinks/day)[4,118-122]	NK	B

Herbal energy drinks (adaptogenic blend *Eleutherococcus senticosus, Schisandra, Panax* species)[123]	NK	C
Heroin[6,26]	NK	C
Intra-arterial thrombolytics for management of stroke[124-126]	6.8–15%	A
Low-molecular weight heparins[127-130]	NK	A
Nicotine[131-133]	Two- to fourfold increased risk	A
Phenylpropanolamine[134-138] Dietary supplements Cough and cold preparations	NK NK	B
Pseudoephedrine[139]	NK	C
Rivaroxaban[140]	0.67%/yr	A
rt-PA for management of ischemic stroke[86,87,141,142]	1.9–10.6%	A
SSRI[47,50,143-146]	0.01%/yr OR 1.32, 95% CI 1.02–1.71	B
High-dose statin[147-153]	NK	B
Thrombolytic therapy for management of acute myocardial infarction[154-156]	0.46–1.9%	A
Warfarin[116,117,157-162]	0.3-1%/yr	A

CI = confidence interval, NK = not known, OR = odds ratio, rt-PA = recombinant tissue plasminogen activator, SSRI = selective serotonin reuptake inhibitor.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Including the herbal source ma huang.

Alcohol abuse remains an important risk factor for ICH with the risk related to the quantity consumed. Individuals who consume 41–120 g (~5 fluid ounces) daily have a 4.6 times higher risk of ICH compared to nondrinkers, and those who consume 121 g or greater daily are at 11.3 times higher risk.[176] Other drugs of abuse have also been implicated in ICH. Cocaine and other sympathomimetics have been implicated in both ischemic stroke and ICH.[77]

Both epidemiological and clinical trials have suggested that very low cholesterol concentrations achieved with high-dose statin therapy are associated with ICH.[147-153] It has been suggested that adequate cholesterol concentrations are necessary to maintain the integrity of the small vessels to prevent rupture.[177] In the Heart Protection Study, there was a trend toward a higher risk of ICH after treatment with simvastatin compared to placebo in patients who had a previous history of stroke or transient ischemic attack (TIA).[178] In the only study to evaluate high-dose statin therapy in primarily ischemic stroke patients (Stroke Prevention by Aggressive Reduction in Cholesterol Levels), patients randomized to atorvastatin had a higher rate of ICH compared to those in the placebo group (HR 1.66, 95% CI 1.08–2.55).[147-152] However, the overall net vascular benefit associated with statins in this trial outweighed the risk of ICH, so it is reasonable to conclude that the majority of ischemic stroke patients receive benefit from statin therapy. A meta-analysis of 31 randomized controlled trials that included 91,588 statin-treated patients found no significant association between statin use and ICH.[179] There are also data from a small study to suggest that continuing statin therapy after ICH is associated with early neurological improvement and reduced 6-month mortality.[180] Currently there is insufficient evidence to provide definitive recommendations regarding the use of statins in ICH patients.[181]

Many drugs theoretically may increase the risk of hemorrhagic stroke, although, for some, such an association has not been reported. Direct thrombin inhibitors such as hirudin or bivalirudin have not been shown to increase the risk of hemorrhagic stroke in clinical trials, and the risk of bleeding associated with these drugs is lower than that associated with heparin.[182] However, clinicians should be aware of the possibility of intracranial hemorrhage associated with these agents, especially when used in combination with other antiplatelet drugs such as the glycoprotein IIb/IIIa receptor antagonists. Intracranial bleeding events have been reported in association with glycoprotein IIb/IIIa receptor antagonists, especially when used in combination with heparin, and are associated with increased mortality.[114] The Abciximab in Emergency Treatment of Stroke Trial, which was terminated prematurely, was designed to evaluate the impact of abciximab on outcome following ischemic stroke. Compared to placebo, abciximab was associated with an increased rate of symptomatic or fatal ICH without improved efficacy.[93] Conflicting information has been reported regarding the risk of bleeding complications associated with the use of enoxaparin for prevention of venous thromboembolism in patients undergoing neurosurgery, but concern has been expressed regarding the use of low molecular weight heparins in this population.[127-129] There was also concern regarding the risk of ICH associated with the use of nonaspirin nonsteroidal anti-inflammatory agents (NANSAIDs). However, a recently published multicenter case-control study did not find an increased risk of ICH associated with NANSAIDs.[183]

Selective serotonin reuptake inhibitors (SSRIs) are used commonly to treat poststroke depression and for facilitating functional recovery after stroke. Observational studies suggest that SSRIs are associated with several adverse effects in older people (age >65 years) including increased risk for ICH (adjusted risk ratio 1.42, 95% CI 1.23–1.64).[146] These data suggest that SSRIs may cause one additional ICH per 10,000 persons (0.01%) treated for 1 year. Recently a cross-sectional epidemiological study of 4,945 patients who received antidepressants found that 5.5% developed cerebral microbleeds, but there was no significant causal relationship between exposure to SSRIs and ICH.[184] For the general population and patients with previous hemorrhagic or ischemic stroke who warrant treatment with an SSRI, there remain insufficient reliable data to make recommendations about any risk of ICH associated with an SSRI, with or without concurrent antiplatelet or anticoagulant therapy.[185]

EPIDEMIOLOGY

Approximately 37,000–52,000 people per year suffer from ICH (approximately 8–13% of all strokes) in the United States.[186] Although ICH only accounts for a small proportion of all strokes, it is associated with the highest mortality rate. Drug-related etiologies can be identified in 14–27% of patients with ICH.[6,62] The incidence of drug-induced hemorrhagic stroke may be increasing.[6] Anticoagulant therapy is implicated in roughly 10% of all cases of ICH. The incidence of hemorrhagic stroke associated with specific drugs is presented in Table 11-7.

MECHANISMS

There are many proposed mechanisms for drug-induced hemorrhagic strokes. Mechanisms by which drugs result in ICH may be multifactorial and are discussed below and presented in **Table 11-8**.

Table 11-8 Mechanisms of Drug-Induced Intracerebral Hemorrhage

Drug	Mechanism(s)
Alcohol abuse Amphetamines Cocaine Ephedra Nicotine Phenylpropanolamine Pseudoephedrine	Acute hypertension
Aspirin Glycoprotein IIb/IIIa inhibitors Heparin High-dose statin Low-molecular weight heparin SSRI Thrombolytics Warfarin	Bleeding diathesis

SSRI = selective serotonin reuptake inhibitor.

ACUTE HYPERTENSION

Acute hypertension is an often under-recognized mechanism, particularly for drug-induced ICH. The primary mechanism behind drug-associated hypertension is related to the effect of drugs on neurotransmitters. Many drugs increase catecholamine release from central noradrenergic nerve terminals (i.e., amphetamines, ephedra, nonprescription sympathomimetics), inhibit reuptake of catecholamines into adrenergic nerve terminals (i.e., cocaine), or increase plasma catecholamine concentrations (i.e., ethanol, cocaine). Hypertension related to drug use may disrupt cerebral autoregulation, promote reperfusion of injured brain tissue, or damage cerebral arterioles, which may eventually rupture.

Ephedra products increase sympathomimetic activity, leading to acute hypertension. In combination with caffeine, ephedrine 20 mg increases systolic blood pressure by 14 mm Hg.[187] Caffeine acts by competitively antagonizing adenosine receptors, thus inhibiting adenosine-mediated dilatation, resulting in vasoconstriction. Caffeine also augments the release of catecholamines, enhancing the effects of ephedra.[188,189] Cigarette smoking acutely elevates blood pressure and reduces cerebral blood flow.[70,71,122] Alcohol acutely and chronically increases blood pressure related to increased adrenergic activity and increased plasma concentrations of cortisol, renin, aldosterone, and vasopressin.[73-75]

BLEEDING DIATHESIS

The mechanism by which anticoagulants increase the incidence of ICH is unclear. Anticoagulants may cause spontaneous subclinical hemorrhages that eventually become clinically significant. Drugs that cause thrombocytopenia (platelets $<50,000 \times 10^3/\mu L$), such as heparin, may increase the risk for drug-induced ICH. Drugs that cause severe hepatic failure or hepatitis may cause clotting derangements and a subsequent risk of ICH. Cocaine and heroin may also induce an illness identical to autoimmune thrombocytopenic purpura that places patients at higher risk of stroke. SSRIs may increase the risk of ICH through their antiplatelet effects.[190] Serotonin in platelets is essential for maintenance of hemostatic functioning and SSRIs deplete platelet serotonin storage leading to attenuation of platelet activity.[191] The antiplatelet effects of SSRIs are considered to be dose-dependent.[143,145]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

It is not possible to distinguish an ischemic stroke from hemorrhagic stroke due to ICH based on clinical examination alone, although several characteristics are more indicative of ICH: headache, impaired level of consciousness, nausea and vomiting, and extreme elevations of blood pressure. Drug-induced hemorrhagic stroke can occur at any time during therapy with a potentially causative agent. Common clinical features of drug-induced ICH are presented in **Table 11-9**.

Table 11-9 Signs and Symptoms Associated with Drug-Induced Intracerebral Hemorrhage

Signs	Symptoms
Brainstem hemorrhage	Altered consciousness Ataxia Coma Difficulty breathing Diplopia Disconjugate gaze Dysmetria Nystagmus
Increased intracranial pressure	Loss of consciousness Nausea/vomiting Sudden headache
Lobar hemorrhage	Aphasia Contralateral sensory-motor deficits Gaze deviation Hemianopia Hemispatial and/or sensory neglect Seizure

Drug-induced hemorrhagic stroke must be distinguished from hemorrhagic stroke due to other etiologies. Conditions to consider in the differential diagnosis of drug-induced ICH are presented in **Table 11-10**. It is difficult to distinguish between drug-induced and nondrug-induced causes of hemorrhagic stroke unless symptoms are temporally related to the ingestion of substances of abuse, quantification drug concentration (i.e., illicit drug screen), or agents with surrogate monitoring parameters (i.e., warfarin or heparin) that can be assessed quantitatively.

Table 11-10 Conditions to Consider in the Differential Diagnosis of Drug-Induced Intracerebral Hemorrhage

- Arterial dissection of the carotid or vertebral artery
- Arteriovenous malformation

- Central nervous system infection/brain abscess
- Cerebral aneurysm
- Encephalitis
- Hemorrhagic conversion of ischemic infarct
- Hypertensive encephalopathy
- Intracranial tumors
- Ischemic stroke
- Metabolic encephalopathy
- Seizure
- Trauma

Diagnosis of stroke consists of a thorough evaluation of patient history, clinical examination, laboratory evaluation, and imaging studies, including CT scan, cerebral angiography, and MRI. Laboratory studies should consist of serum electrolyte and glucose concentrations, complete blood count, coagulation parameters, and drug screen evaluation. A CT scan is essential to differentiate between ischemic and hemorrhagic stroke.

RISK FACTORS

Risk factors for drug-induced ICH are presented in **Table 11-11**. Thrombolysis has become a mainstay of therapy for both acute myocardial infarction and acute ischemic stroke. Although this therapy improves morbidity and mortality in these patients, there is an inherent risk of ICH. Risk factors for ICH associated with thrombolytic therapy following acute myocardial infarction include advanced age, female, African-American, systolic blood pressure ≥160 mm Hg, diastolic blood pressure ≥100 mm Hg, previous stroke, rt-PA dose >1.5 mg/kg, and low body weight (≤50 kg).[192] Risk of thrombolysis-related ICH in patients with acute ischemic stroke include NIH Stroke Scale score >20 (severe stroke), advanced age, thrombocytopenia, early infarct signs on pretreatment CT scan, increased time to treatment, history of heart failure, elevated serum glucose (>200 mg/dL), low plasminogen activator inhibitor concentration, history of diabetes mellitus and cardiac disease, increasing stroke severity, use of antiplatelet agents other than aspirin, elevated pretreatment mean blood pressure, and lower platelet counts.[165,193] In addition, use of rt-PA in patients that do not meet the inclusion criteria and/or meet exclusion criteria detailed in the National Institutes of Neurological Diseases Study—especially administration of rt-PA to patients that present >4.5 hours from the onset of symptoms—increases the risk of ICH in patients with acute ischemic stroke.[194,195] The GRASPS (Glucose Race Age Sex Pressure Stroke Severity) clinical risk score is a validated scoring system for predicting risk of symptomatic ICH after receiving rt-PA.[196] This score includes six predictor variables: glucose at presentation, race (Asian), age, sex (male), systolic blood pressure at presentation, and severity of stroke at presentation (NIHSS). The score calculator can be accessed at the following site: http://www.strokeassociation.org/STROKEORG/General/Get-With-The-Guidelines-Stroke-sICH-Calculator_UCM_453748_SubHomePage.jsp.

Table 11-11 Risk Factors for Drug-Induced Intracerebral Hemorrhage

General risk factors

- Age >65 years
- History of hypertension
- Amyloid angiopathy
- Cigarette smoking
- Sedentary lifestyle
- Coagulation disturbances
- Thrombocytopenia

Aspirin-induced intracerebral hemorrhage[99]

- History of stroke
- Hypertension
- Age >75 years
- Race (black population)
- Dose ≥650 mg/day
- Amyloid accumulation
- Epistaxis
- Concurrent use with anticoagulants
- Neoplasm
- Vascular malformations or aneurysms

Oral anticoagulant-induced intracerebral hemorrhage[200]

- Advanced age (>85 years)
- Previous cerebral ischemic event
- Cerebral amyloid angiopathy
- Addition of antiplatelet agents
- Intensity of anticoagulation
- Duration of therapy
- History of bleeding
- Drug interactions
- Time in therapeutic range
- Kidney disease

Intra-arterial thrombolytic-induced intracerebral hemorrhage[209]

- National Institutes of Health Stroke Scale >20
- Longer time to recanalization
- Lower platelet count
- Hyperglycemia

Intravenous thrombolytic-induced intracerebral hemorrhage[193,208]

- Severity of neurologic deficit at time of presentation (measured by National Institutes of Health Stroke Scale >20)
- Thrombolytic dose used for ischemic stroke (>0.9 mg/kg or 90 mg)
- Early signs of infarction with brain edema or mass effect on imaging studies
- Age >80 years
- Hypertension
- Timing of revascularization therapy (i.e., longer stroke onset-to-treatment times)
- Hyperglycemia (glucose >200 mg/dL) or history of diabetes
- Coadministration of antithrombotic agents
- History of heart failure
- Thrombocytopenia

Heparin-induced intracerebral hemorrhage

- Hypertension
- Use of bolus dosing
- Thrombocytopenia
- Size of stroke

Low molecular weight heparin and glycoprotein IIb/IIIa inhibitor-induced intracerebral hemorrhage

- Age >75 years
- Kidney disease
- Thrombocytopenia

Selective serotonin reuptake inhibitor-induced intracerebral hemorrhage[47]

- Heavy alcohol use
- Cigarette smoking
- Vulnerability to bleeding diathesis

High-dose statin-induced intracerebral hemorrhage[147,149]

- Age >65 years
- Stage 2 hypertension
- Middle-aged men
- Previous ischemic stroke or transient ischemic attack

The FDA banned phenylpropanolamine, which was marketed in combination with caffeine as a weight-loss aid, after numerous adverse cardiovascular and central nervous system events.[137] Used in combination, these drugs have an additive effect on blood pressure.[197] Women between the ages of 18 and 49 years who use phenylpropanolamine as an appetite suppressant are 17 times more likely to experience an ICH compared with women of that age group that do not take this medication.[138] The risks associated with cough and cold preparations are less clear. The risks in men taking phenylpropanolamine are also unclear because the case-control study included too few men from which to draw conclusions.[137] The association between sympathomimetic drugs and ICH appears to be dose-related and additive when used in combination with other agents with similar activity. Patients receiving phenylpropanolamine in cough and cold products were three times more likely to develop ICH than those patients not receiving these products.[137,198] Herbal preparations that contain ephedra or ma huang also increase the risk of ICH in a dose-related fashion. The risk of ICH is fourfold greater in patients receiving ephedra doses >32 mg/day than those receiving no ma huang or lower doses.[108,109,199] This is an important issue with respect to counseling of patients regarding nonprescription drug products or the use of herbal supplements/energy drinks that may have sympathomimetic effects.

Anticoagulant therapy is used commonly to treat many thromboembolic disorders, particularly in the elderly population. Patients with an INR >3 or an activated partial thromboplastin time (aPTT) >80–90 seconds are at increased risk of ICH associated with warfarin and heparin, respectively. Factors that increase the risk of anticoagulant-related ICH include advanced age, level of anticoagulation, prior stroke, and hypertenson.[117,159,200] The risk for ICH with warfarin therapy is particularly high at age ≥85 years. INR <2 is not associated a with lower risk of ICH compared with INR between 2 and 3, but the risk is increased with INR >3.5, which should be avoided.[117,157,200] Therefore, for prevention of recurrent ischemic stroke, warfarin therapy should be focused on maintaining INR between 2 and 3.[117] The risk of anticoagulant-related bleeding is highest during the first month of therapy.[201] The HAS-BLED score has been validated to assess the bleeding risk in atrial fibrillation patients and assigns one point for the presence of each of the following: hypertension (uncontrolled systolic blood pressure >160 mm Hg), abnormal renal and/or liver function, previous stroke, bleeding history or predisposition, labile INR, elderly (age >65 years), and concomitant drugs (antiplatelets or nonsteroidal anti-inflammatory drugs) and/or alcohol excess. The HAS-BLED scores range from 0 to 9 with scores ≥3 indicating the highest risk of bleeding.[167] There is an increased rate of cerebral bleeding associated with intermittent intravenous heparin therapy compared with that associated with continuous intravenous infusion. Subcutaneous heparin is associated with bleeding rates similar to those due to continuous intravenous infusion.[115,117] Increased bleeding incidences have been reported in patients in whom aPTT is prolonged to more than twice the upper limit of the therapeutic range in at least 50% of the tested samples. For every 10-second increase in aPTT, major bleeding complications are increased by 7%.[117]

Patients with acute kidney injury or chronic kidney disease (serum creatinine >2 mg/dL) are at greater risk of bleeding associated with low molecular heparins or glycoprotein IIb/IIIa receptor antagonists than patients with normal kidney function.[202,203] Many of these agents are excreted renally and may accumulate in patients with kidney disease. Dose adjustments may be necessary; however, there currently are no published data regarding the optimal dosing regimen in patients with kidney disease. Patients ≥75 years of age have a higher rate of ICH after treatment with glycoprotein IIb/IIIa receptor antagonists.[113]

The use of aspirin for both primary and secondary prevention of vascular events including ischemic stroke has been associated with increased risk of ICH (RR 1.35).[99] Because significant benefit is achieved with the use of aspirin, evaluation of possible risk factors for ICH may assist in judging if the risk exceeds the benefit. Risk factors for aspirin-induced ICH include age (older than 75 years), race (black), hypertension, amyloid accumulation, history of epistaxis, high dose (>650 mg/day), bleeding disorders, and neoplasm.[99]

Use of combinations of agents such as antiplatelet drugs, anticoagulants, or thrombolytics may provide additive beneficial effects in patients with heart disease or stroke or TIAs, but these combinations also increase the risk of ICH. Concomitant use of aspirin with warfarin or heparin and glycoprotein IIb/IIIa antagonists is associated with an increased incidence of bleeding.[117] The use of combinations of oral antiplatelet agents for secondary prevention of stroke or acute coronary syndromes has become a common practice, based on the results of clinical trials showing additive benefit when combining therapy with extended-release dipyridamole or clopidogrel with aspirin. However, a study that evaluated the combination of aspirin and clopidogrel for prevention of recurrent stroke or TIA reported an absolute 1.3% increase in the risk of life-threatening bleeding. This combination therapy was not associated with a reduction in vascular events, so the risks of the combination therapy appeared to outweigh the benefits.[204] There are newer ongoing trials that are assessing the safety of short-term use of dual antiplatelet drugs following minor stroke or TIA that will identify the risk-benefit ratio.

Table 11-12 Approaches to Help Prevent Drug-Induced Intracerebral Hemorrhage

Drug	Condition	Prevention
Alcohol	Moderation	Men should consume no more than 2 drinks/day and nonpregnant women should consume no more than 1 drink/day Control hypertension
All drugs	General risk factor modification	Control of hypertension (blood pressure <130/80 mm Hg) Discontinue drugs known to be associated with stroke in patients at high risk
Cigarette smoking	Smoking cessation	Encourage patient and family to stop smoking Provide counseling, nicotine replacement and formal programs

Substance abuse	Cessation	Rehabilitation program
Target specific oral anticoagulants		Control of hypertension Combination of aspirin and clopidogrel may accentuate ICH risk Evaluate for potential drug interactions
Thrombolytic therapy	Assess risk benefit and monitor patients closely	Follow recommended inclusion/exclusion selection criteria outlined in acute ischemic stroke guidelines[85]
Warfarin[102]	Assess risk benefit and monitor patients closely	Maintain INR <3 Control of hypertension Caution in elderly patients who are at highest risk Avoid combinations of warfarin with antiplatelet agents Evaluate for potential drug interactions

ICH = intracerebral hemorrhage, INR = international normalized ratio.

MORBIDITY AND MORTALITY

ICH accounts for only a small percentage of all stroke cases but is associated with the highest incidence of mortality (in-hospital mortality of ~34%). Therefore, the mortality rates associated with drug-induced ICH may be high.

PREVENTION

The most effective means of prevention of drug-induced stroke is avoidance of agents known to be associated with ICH, especially in high-risk patients. Strategies for prevention of drug-induced hemorrhagic stroke are listed in **Table 11-12**. Patients receiving anticoagulant therapy should be closely monitored for intensity of anticoagulation, kidney function, and the possibility of drug interactions. Careful selection of ischemic stroke patients as candidates to receive intravenous rt-PA is also important. However, the mainstay of prevention is patient education and identification of risk factors, particularly in those patients that are at high risk.[181]

MANAGEMENT

The management of any ICH patient has many phases: prevention of ICH, supportive and medical management during the acute phase, measures to mitigate the ongoing pathologic process, and rehabilitation. In addition, discontinuation of the offending agent (if identified) is essential.

All patients with acute drug-induced ICH should be hospitalized, and most require care in an intensive care unit. Guidelines for the management of patients with ICH have been published previously.[181] Patients with ICH often present with severe acute hypertension. There is no consensus regarding the ideal target range for blood pressure control. The decision regarding the appropriate target lower blood pressure is a balance between minimizing hematoma volume and preventing ischemic changes. There is an ongoing study to assess the efficacy of early (within 4.5 hours of symptom onset) intensive blood pressure lowering (systolic blood pressure <140 mm Hg) for improving outcome after ICH. Until completion of this study, guidelines suggest that, in patients presenting with systolic blood pressure between 150 and 220 mm Hg and without contraindication to acute intervention, lowering blood pressure to a systolic pressure of 140 mm Hg is safe. For those presenting with systolic blood pressure above 220 mm Hg, blood pressure should be reduced aggressively via continuous intravenous infusion of antihypertensive agents.[181] Surgical evacuation of the hematoma may be necessary in some patients. General medical management and supportive care are indicated for all patients to prevent complications (i.e., intracranial hypertension, hyperthermia, hyperglycemia).[181]

If ICH occurs in the setting of thrombolytic, anticoagulant, or antiplatelet therapy, immediate cessation of therapy with the causative agent is indicated, with rapid reversal of the impaired clotting profile. Patients with ICH who are receiving unfractionated heparin or low-molecular weight heparin should receive protamine sulfate (1 mg/100 units of heparin or 1 mg of enoxaparin). The dose of protamine should be adjusted according to the time elapsed from last heparin dose. For example, if heparin was discontinued within the previous 30–60 minutes, the protamine dose is 0.5–0.75 mg/100 units of heparin; if the heparin infusion was discontinued within the previous 60–120 minutes, the protamine dose is 0.375–0.5 mg/100 units of heparin; if the heparin infusion was discontinued more than 120 minutes ago, the protamine dose is 0.25–0.375 mg/100 units of heparin. Protamine sulfate should be administered intravenously over 10 minutes in doses not to exceed 50 mg because of the potential risk of severe systemic hypotension.[181] Patients with bleeding caused by platelet dysfunction should receive platelet transfusions (6 units) and/or a single dose of desmopressin (0.3 mcg/kg). For ICH related to thrombolytic therapy, the currently recommended management is platelet infusion (6–8 units) and cryoprecipitate that contains factor VIII.[181]

Patients who are receiving warfarin with INR elevation and experiencing ICH should undergo INR reversal immediately. The treatment options include fresh frozen plasma (FFP), prothrombin-complex concentrates (PCCs), activated PCC FEIBA (factor VIII inhibitor bypassing activity), vitamin K, and recombinant activated factor VIIa (rFVIIa).[205] Therapy should never be withheld to check coagulation profiles because normalization of the INR with some of these approaches may require several hours. Administration of PCCs normalizes the INR more rapidly than FFP, and PCCs can be given in smaller volumes, thus decreasing the risk of heart failure exacerbation associated with FFP. Therefore, PCCs may be preferred over FFP.[181] Recombinant activated factor VIIa does not replace all clotting factors and, although the INR may be lowered, clotting may not be restored in vivo; therefore rFVIIa is not recommended for warfarin reversal in patients with ICH.[181] Administration of intravenous vitamin K alone is insufficient for warfarin reversal during the first hours, but should be part of all acute warfarin reversal strategies at a dose of 5–10 mg.

Idarucizumab is currently the only antidote available for reversing the effects of the target-specific oral anticoagulants (specifically dabigatran). However, other antidotes, including andexanet alfa and aripazine, have been developed and have shown promise in early clinical trials evaluating their efficacy and safety for reversal of factor Xa inhibitors.[206] The newer target-specific oral anticoagulants are different from warfarin in that they have relatively short half-lives of 5–15 hours in patients with normal kidney function. Evaluation of prothrombin time with selected agents (apixaban, rivaroxaban, edoxaban) and thrombin time (dabigatran) may be helpful for individualization of care. Until the newer antidotes are available, potential reversal strategies for apixaban, rivaroxaban, and edoxaban include using FEIBA, PCCs, or rFVIIa.[207] Fresh frozen plasma and vitamin K are not useful for reversal of the target-specific oral anticoagulants. Activated charcoal can be used if the most recent dose of these drugs was taken within 2 hours. Hemodialysis is also another option for management of ICH associated with dabigatran, but less so for the other agents because they are more highly protein bound.[181] For a more complete review of reversing the effects of antithrombotic agents, please refer to the guidelines from the Neurocritical Care Society published in 2016.[210]

A difficult decision after anticoagulation-induced ICH is deciding whether to reinitiate anticoagulant therapy. There are no strict guidelines on the length of time to withhold anticoagulation therapy following ICH. Avoidance of oral anticoagulation for at least 4 weeks in patients without mechanical heart valves might decrease the risk of ICH recurrence. The guidelines also recommend avoidance of long-term anticoagulation with warfarin in patients with nonvalvular atrial fibrillation after warfarin-associated spontaneous lobar ICH because of the high risk of recurrence.[181] The safety of the target-specific oral anticoagulants in patients with atrial fibrillation and past ICH is unknown.

INFORMATION FOR PATIENTS

Risk factor assessment of patients and drug profile review for potential drug interactions is essential for prevention of drug-induced ICH. Because patients do not obtain many of the drugs that are known to cause ICH at pharmacies, it is extremely important that patients at risk are counseled to consult their healthcare professionals before purchasing nonprescription drug or herbal products. For example, patients with hypertension should be advised that cough and cold products or herbal products, including energy drinks may contain sympathomimetic agents that could place them at increased risk for drug-induced hemorrhagic stroke. Prevention of head injury is very important, especially when patients are taking anticoagulants or antiplatelets that might cause intracranial bleeding if they hit their head. It is important that patients realize they can still have a healthy active lifestyle, but just be cautious of activities (e.g., skiing, hockey, soccer) that might place them at high risk for falling or hitting their head. Patients receiving combinations of agents that are known to cause hemorrhagic stroke (such as anticoagulants and aspirin) should be informed regarding the increased risk. Patients should be instructed to inform their healthcare professionals of all medications that they are taking, to facilitate a full evaluation of potential agents that may be associated with drug-induced hemorrhagic stroke. It is important for patients to closely adhere to the regimens prescribed including scheduled laboratory monitoring to minimize the risk associated with the use of some of these agents.

CHAPTER 12

Movement Disorders

Jack J. Chen, Khashayar Dashtipour, and David M. Swope

In the United States and across the globe, drug-induced movement disorders (DIMDs) are a significant iatrogenic burden among selected patient populations, such as those receiving psychotropic agents for psychiatric disorders or antiemetic drugs (e.g., droperidol, metoclopramide, prochlorperazine) for gastrointestinal disorders.[1] DIMDs refer to a variety of distinct, treatment-emergent, involuntary movements, including akathisia, tardive dyskinesia (TDk), dystonia, and parkinsonism, which may interfere with medication adherence, performance of motor tasks, and psychosocial interactions. In patients with psychiatric disorders, DIMDs are a significant source of distress and discomfort resulting in medication nonadherence or refusal, subsequent relapse and rehospitalization, and increased use of healthcare resources.[2] In one study, patients with schizophrenia or schizoaffective disorder in whom antipsychotic-induced DIMD developed were 40 times more likely to discontinue maintenance medication therapy.[3] DIMDs are under-recognized iatrogenic conditions. In one study, resident physicians failed to detect or recognize more than 50% of cases of TDk and drug-induced parkinsonism.[4]

DIMDs can be described as acute or tardive. Acute DIMDs (e.g., acute akathisia, acute dystonia) occur within hours to days after exposure. Tardive (i.e., delayed onset) DIMDs (e.g., tardive akathisia, TDk, tardive dystonia) occur months to years after drug exposure. Patients with DIMDs commonly present with two or more coexistent movement disorders.[5,6] Examples of DIMD combinations include TDk with parkinsonism, TDk with tardive dystonia, and TDk with akathisia.

Soon after the introduction of conventional antipsychotics in the 1950s, it became obvious that these agents were a cause of iatrogenic movement disorders. These DIMDs were termed *extrapyramidal symptoms* (EPS) or *side effects*, which implies the involvement of extrapyramidal regions (i.e., basal ganglia and thalamus) as opposed to the corticospinal pyramidal motor system. Subsequently, as induction of EPS became viewed as a typical and expected correlate to antipsychotic efficacy, the term *neuroleptic* ("seize the nerves") was coined.[7] The introduction of clozapine, an antipsychotic nearly devoid of EPS, in the late 1980s demonstrated that development of EPS was not a requisite for antipsychotic efficacy, and thus the newer antipsychotics are referred to as atypical. It is important to note that EPS is not synonymous with DIMDs. The former refers collectively to drug-induced dystonia, parkinsonism, and TDk. Drug-induced akathisia is considered a DIMD but not an EPS.

It has been clearly established that atypical antipsychotics are associated with a significantly lower risk of DIMDs compared with that associated with conventional neuroleptics (with or without concurrent antimuscarinic prophylaxis).[8-13] However, among the category of atypical antipsychotics, differences in risk of EPS exist. Clozapine and pimavanserin are associated with the lowest risk of EPS. Lurasidone, olanzapine, paliperidone, risperidone, and ziprasidone are associated with higher risks of dose-dependent EPS.

Movement disorders are also associated with other psychotropic drugs, such as lithium, selective serotonin reuptake inhibitors (SSRIs), psychostimulants, and tricyclic antidepressants (TCAs). Tremor commonly occurs in association with lithium treatment, which also occasionally causes chorea.[14] Treatment with SSRIs may cause akathisia and tremor, but rarely induces dyskinesia, dystonia, or parkinsonism.[15,16] Psychostimulants (e.g., amphetamine, methylphenidate, pemoline) have occasionally been reported to produce a variety of movement disorders such as dyskinesias, dystonia, stereotypic behavior, and tics.[17] The most common movement disorders associated with TCAs are akathisia, myoclonus, and tremor.[18,19] Antiepileptic agents rarely induce movement disorders, with the exception of valproate, which is frequently associated with tremor and, to a lesser extent, parkinsonism. Carbamazepine, ethosuximide, felbamate, gabapentin, phenobarbital, and phenytoin have rarely been associated with dyskinesia or dystonic reactions.[20] For many years, chorea has been recognized as a complication of estrogen- and progesterone-containing products (e.g., oral contraceptives).[21]

Antiemetics that block central dopamine receptors (i.e., droperidol, metoclopramide, prochlorperazine) are also commonly implicated in the various DIMDs.[22-25]

Drug-induced tremor, although not uncommon, will not be discussed in this chapter, and readers are referred elsewhere for further reading.[26] Readers are also referred elsewhere for discussions on drug-induced myoclonus (abrupt, brief, and sudden “shock-like” involuntary movements), levodopa-induced dyskinesias, neuroleptic malignant syndrome, restless legs syndrome, and motor tics.[27-32] The primary topics that will be covered in this chapter are drug-induced akathisias, TDk, dystonias, and parkinsonism.

AKATHISIA (ACUTE AND TARDIVE)

The term *akathisia* is derived from Greek (“not sitting still”), and was initially used at the turn of the 20th century to describe the restlessness and pacing observed in patients diagnosed with hysteria and neuroses. Akathisia is now used extensively to describe the restlessness and pacing behavior induced by neuroleptics and other drugs. Akathisia induced by psychotropic agents can be a distressing adverse effect, resulting in poor treatment adherence and, consequently, an increased risk of relapse or exacerbation of the underlying psychiatric disorder.

CAUSATIVE AGENTS

Agents implicated in drug-induced akathisia are listed in **Table 12-1**.[24,25,33-44] Conventional neuroleptics and antidopaminergic antiemetics are the most commonly implicated drugs in acute and tardive akathisia. Several atypical antipsychotics also induce akathisia, albeit with lower incidences as compared with conventional neuroleptics. The SSRIs and the serotonin–norepinephrine reuptake inhibitor mirtazapine are also commonly implicated in acute akathisia, but rarely in tardive akathisia.

EPIDEMIOLOGY

Acute akathisia occurs in 20–30% of patients taking conventional neuroleptics but has been reported in up to 76% of patients.[34-36] The incidence of tardive akathisia is approximately 30%.[36]

The atypical antipsychotics (e.g., aripiprazole, clozapine, iloperidone, olanzapine, paliperidone, quetiapine, risperidone, ziprasidone) also induce akathisia, although the risk is lower than that associated with conventional neuroleptics. In one study, the prevalence of akathisia associated with clozapine, risperidone, and conventional neuroleptics was 7.3%, 13%, and 23.8%, respectively.[37] However, at daily doses >6 mg, the frequency of risperidone-induced akathisia increases significantly. The incidence of akathisia in iloperidone-treated patients is low and similar to that of placebo.[38,39]

Table 12-1 Agents Implicated in Drug-Induced Akathisia

Drug	Incidence	Level of Evidence[a]
ANTIEMETICS/GASTRIC MOTILITY AGENTS		
Droperidol[24]	20–30%	B
Metoclopramide[24,25]	20–30%	B
Prochlorperazine[24]	20–30%	B
Promethazine[33]	20–30%	B
ANTIEPILEPTICS		
Carbamazepine[41]	NK	C
PSYCHOTROPICS		
Amoxapine[42]	NK	C
Atypical antipsychotics[37-39,b]	5–15%	A
Conventional neuroleptics[34-37,c]	20–30%	A
Lithium[43]	NK	C
Selective serotonin-reuptake inhibitors[40,d]	5%	B
Tricyclic antidepressants[44,e]	5%	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Amisulpride, aripiprazole, asenapine, brexpiprazole, cariprazine, clozapine, iloperidone, lurasidone, olanzapine, paliperidone, quetiapine, risperidone, sertindole, ziprasidone.

[c] Chlorpromazine, fluphenazine, haloperidol, mesoridazine, molindone, perphenazine, promazine, thioridazine, thiothixene, trifluoperazine, triflupromazine.

[d] Citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline.

[e] Amitriptyline, clomipramine, desipramine, doxepin, imipramine, nortriptyline.

Akathisia is also induced by SSRIs and TCAs. Although the incidence of SSRI- and TCA-induced akathisia has not been studied systematically, it appears to occur in at least 5% of patients treated with SSRIs, with higher rates associated with stimulating SSRIs (e.g., fluoxetine, paroxetine).[40] Treatment-emergent anxiety, agitation, and restlessness are commonly reported in association with antidepressants (especially within the first 2 weeks of initiating treatment), and it is possible that a subset of these patients are experiencing akathisia.

Akathisia also frequently occurs in association with antidopaminergic antiemetics. In one study, acute, transient akathisia occurred in 71.4%, 25%, 35.3%, and 11.1% of patients treated with droperidol, metoclopramide, prochlorperazine, and placebo, respectively.[24] Rapid intravenous infusion of metoclopramide is associated with a higher incidence of akathisia compared with slow infusion.[25]

MECHANISMS

The pathophysiologic mechanism of drug-induced acute akathisia is not well understood, but involves altered dopaminergic and serotonergic activity (**Table 12-2**). This theory is supported by the observation that akathisia is a well-recognized effect of centrally-acting dopamine-receptor–blocking agents (DRBAs). The dopaminergic pathway of the mesolimbic tract appears to be affected, and the stronger the antidopaminergic effect of a drug, the higher the incidence of akathisia.[45] Serotonergic and noradrenergic input in the ventral tegmental area exerts an inhibitory effect on mesocortical dopamine transmission. This is supported by the observation that akathisia may be caused by serotonergic agents such as SSRIs, and the positive therapeutic response to antiserotonergic therapies such as 5-hydroxytryptophan (serotonin) type 2 (5-HT_2) receptor blockers (e.g., cyproheptadine) and the noradrenergic β-receptor blocker propranolol (which also possesses antiserotonergic activity). In addition, the atypical antipsychotics, which also block 5-HT_2 receptors, are associated with lower rates of akathisia compared to those of conventional neuroleptics. Iron deficiency has been implicated as a component of the pathophysiologic mechanism for akathisia, but the data are inconsistent.[46] The mechanism underlying the tardive form of akathisia is less well understood, but is probably distinct from that of acute akathisia.

Table 12-2 Mechanisms of Drug-Induced Akathisia

Drug	**Mechanism**
Amoxapine Atypical antipsychotics[a] Conventional neuroleptics[b] Droperidol Metoclopramide Prochlorperazine Promethazine	Postsynaptic blockade of dopamine type 2 receptors in the mesocortical pathway
Selective serotonin reuptake inhibitors[c] Tricyclic	Stimulation of 5-hydroxytryptophan (serotonin) type 2 receptors in the ventral tegmental area, resulting in

antidepressants[d]	hypofunction of the dopaminergic mesocortical pathway
Carbamazepine Lithium	Unknown

[a] Amisulpride, aripiprazole, asenapine, brexpiprazole, cariprazine, clozapine, iloperidone, lurasidone, olanzapine, paliperidone, quetiapine, risperidone, sertindole, ziprasidone.

[b] Chlorpromazine, fluphenazine, haloperidol, mesoridazine, molindone, perphenazine, promazine, thioridazine, thiothixene, trifluoperazine, triflupromazine.

[c] Citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline.

[d] Amitriptyline, clomipramine, desipramine, doxepin, imipramine, nortriptyline.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

According to the *Diagnostic and Statistical Manual of Mental Disorders*, 5th Edition (*DSM-V*), medication-induced akathisia is comprised of both a subjective and an objective component.[47] The core features are subjective symptoms of restlessness (commonly referable to the legs) and at least one of the following objective findings: fidgety movements or leg swinging while seated, marching on the spot while standing, rocking from one foot to another, pacing to relieve subjective restlessness, or an inability to sit or stand still for several minutes (**Table 12-3**). Subjective dysphoria is a major component of neuroleptic-induced akathisia and includes apprehension, an inner sense of restlessness (often in the legs), anxiety, and the urge to move. Significant mental distress is experienced if the patient is asked to not move or is restrained from moving. Unlike most movement disorders, which are involuntary, the movements associated with akathisia (e.g., fidgeting, leg or body shifting, toe tapping, walking) are voluntary, and occur in response to the subjective feeling of restlessness or discomfort. As with other movement disorders, anxiety or stress exacerbates pre-existing akathisia.

Symptoms of acute akathisia may occur within an hour (as with intravenously administered antidopaminergic antiemetics) to within several weeks of initiating or increasing the dose of the offending drug, and may also develop after neuroleptic therapy cessation or dose reduction (i.e., withdrawal akathisia). Occasionally, the discontinuation of therapy with a concurrent antiakathisia agent (e.g., propranolol) may unmask akathisia. Although the temporal criteria for tardive akathisia are debatable, the onset of symptoms after 3 months of stable drug therapy is considered tardive.

Table 12-3 Signs and Symptoms Associated with Drug-Induced Movement Disorders

Akathisia

- Subjective feeling of restlessness and need to move
- Objective symptoms of pacing, walking in place, foot or toe tapping, rocking while seated
- Distress if restrained or unable to move
- Symptoms may improve during sleep or in a supine position

Tardive dyskinesia

- Abnormal involuntary choreoathetoid movements affecting the orofacial region, tongue, upper and lower extremities, and trunk
- Symptoms are not painful but may result in embarrassment in social settings and difficulty with chewing, speaking, and swallowing
- Lip smacking, chewing movements, and tongue protrusion are common

Dystonia

- Sustained involuntary muscle contractions or spasms resulting in abnormal postures or twisting and repetitive movements
- Affected body parts include the neck, upper and lower extremities, jaw, larynx, and trunk
- Symptoms associated with distress, pain, and disability
- Difficulty with walking, breathing, head turning, speech, and swallowing

Parkinsonism

- Tremor, rigidity, slowness of movement affecting bilateral upper and lower extremities, and truncal regions
- Masked facies, micrographia, slow shuffling gait, and stooped posture

---

Drug-induced akathisia may be mistaken for anxiety, psychotic agitation, drug withdrawal symptoms, or restless legs syndrome (**Table 12-4**). Acute drug-induced akathisia should be suspected if symptoms develop soon after the initiation of therapy with potentially causative drugs and in the absence of other conditions associated with restlessness. In contrast to restless legs syndrome, patients with akathisia may report improvement when lying down or sleeping, absence of lower extremity paresthesias, absence of diurnal pattern, and absence of periodic leg movements in sleep.

Table 12-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Movement Disorders

Akathisia

- Alcohol or drug withdrawal
- Anxiety disorder
- Psychic agitation
- Restless legs syndrome

Tardive dyskinesia

- Edentulism
- Huntington disease

- Hyperthyroidism
- Levodopa-induced dyskinesia
- Neuroacanthocytosis (choreoacanthocytosis)
- Sydenham chorea
- Wilson disease

Dystonia

- Arthritis
- Atlantoaxial rotary subluxation
- Catatonia
- Conversion reaction
- Dopa-responsive dystonia
- Huntington disease
- Idiopathic dystonia
- Inherited dystonias
- Neuroleptic malignant syndrome
- Orthopedic disorder
- Tetanus
- Wilson disease

Parkinsonism

- Essential tremor
- Hypothyroidism
- Parkinson disease (nondrug-induced)
- Severe depression
- Wilson disease

Tardive akathisia may be suspected in the absence of other conditions associated with restlessness. The symptoms of tardive akathisia are similar to those of acute akathisia, except that patients with tardive akathisia tend to report less distressing subjective symptoms and are able to suppress movements or remain still for longer periods. The Barnes Akathisia Rating Scale (BARS) may be used for akathisia detection and assessment.[48] The BARS is a clinician-rated assessment tool, composed of four items used to assess the presence and severity of drug-induced akathisia. The BARS rates both objective items (e.g., observed restlessness) and subjective items (e.g., patients' awareness of restlessness and related distress), in addition to a global clinical assessment of akathisia.

RISK FACTORS

Risk factors for drug-induced akathisia are not well described, but include older age, concurrent mood disorder (e.g., anxiety, bipolar disorder, depression), cognitive impairment, female sex, history of akathisia, intellectual disability, iron deficiency, presence of negative symptoms of schizophrenia, use of high-dose neuroleptics, rapid neuroleptic dose escalation, and use of high-potency neuroleptics (**Table 12-5**).[36,37,49]

Table 12-5 Risk Factors for Drug-Induced Akathisia

- Advanced age
- Cognitive impairment
- Female sex
- High dose neuroleptic therapy
- High potency neuroleptic therapy
- History of akathisia
- Intellectual disability
- Iron deficiency
- Mood disorder
- Presence of negative symptoms of schizophrenia
- Rapid neuroleptic dose escalation

MORBIDITY AND MORTALITY

When left untreated, the symptoms of acute drug-induced akathisia may gradually subside or may fluctuate over time. In some patients, acute akathisia may become chronic and persist for months or years. Acute akathisia has been associated with promoting aggression, suicidal behavior, and treatment nonadherence in patients with schizophrenia.[50-52] Worsening of anxiety and aggressive behavior may result in an increase in neuroleptic dose, which in turn may exacerbate the underlying akathisia. Although tardive akathisia may slowly remit upon drug discontinuation, it often persists.

PREVENTION

Approaches to help prevent drug-induced akathisia are summarized in **Table 12-6**. As with most drug-induced diseases, prevention is very important. Primary prevention aided by knowledge and recognition of risk factors is a key factor for minimizing the burden of akathisia. The necessity of short- or long-term use of potentially causative agents should be carefully evaluated. If indicated, the lowest effective dose should be used, and patients should undergo regular evaluations for emergence of akathisia. Standardized titration of doses of antipsychotic agents to avoid excessive dose escalation and the use of atypical antipsychotics are successful means of prevention. Although iron deficiency has been associated with acute and tardive akathisia, routine iron supplementation as a preventive or treatment intervention is not supported by available evidence.[53] In patients at high risk of akathisia (e.g., history of akathisia), concurrent administration of an antimuscarinic agent or β-blocker is reasonable.

Table 12-6 Approaches to Help Prevent Drug-Induced Akathisia

Amoxapine, atypical antipsychotics, conventional neuroleptics, lithium, metoclopramide

- Use lowest effective dose
- Use standardized dose titration to avoid excessive dose escalation
- Correct underlying iron deficiency
- If high risk for akathisia (e.g., prior history of akathisia) exists, concurrent administration of an antimuscarinic agent or β-blocker is recommended

Droperidol, prochlorperazine, promethazine, selective serotonin reuptake inhibitors, tricyclic antidepressants

- Use lowest effective dose

Carbamazepine

- None known

MANAGEMENT

Early detection is a key factor in the probability of eventual remission of drug-induced akathisia. If treatment with an implicated agent has been extended for 3 months or longer, the patient should be examined periodically to determine the presence of subjective and objective features of akathisia. When akathisia is detected, several management approaches can be initiated (**Table 12-7**).

Table 12-7 Management of Drug-Induced Akathisia

- Discontinue or reduce dose of causative agent
- If due to neuroleptic, switch to an atypical antipsychotic
- Consider trial of antimuscarinic agent or nonselective β-blocker (i.e. propranolol)
- Miscellaneous other agents may be effective (amantadine, benzodiazepine, clonidine, cyproheptadine, mianserin, mirtazapine)

For patients with acute akathisia, the causative agent should be discontinued, if possible. For neuroleptic-treated patients, a switch to an atypical antipsychotic or alternative agent should be considered. In patients in whom causative agents have been discontinued, the akathisia may promptly resolve, only to be replaced with increased agitation and anxiety. Care should be taken to differentiate these symptoms from those of persistent akathisia. Administration of a lipophilic β-blocker, such as propranolol, is effective and well-tolerated.[54] β_2-receptor inhibition appears to be crucial for efficacy, as β_1-receptor selective agents are less effective.[55] However, a trial of a cardioselective, β_1-receptor blocker is reasonable if β_2-blockade is undesirable. The hydrophilic β-blockers (e.g., atenolol, nadolol) do not appear to be effective. β-blockers should be avoided in patients with a history of cardiac conduction blocks, orthostatic hypotension, or reactive airway disease. Administration of antimuscarinic agents (e.g., benztropine, diphenhydramine), benzodiazepines, or antiserotonergic agents (cyproheptadine) is also effective and may be preferable if sedation is desired.[54,56-58] However, these agents should be used with caution in elderly patients with cognitive impairment. Less commonly used agents include amantadine, amitriptyline, clonidine, mianserin, mirtazapine, and mild opioids (e.g., codeine or propoxyphene).[59-64]

Treatment of drug-induced tardive akathisia is difficult, as no drug therapy consistently provides benefit. If possible, therapy with the suspected agent should be discontinued, or modification of therapy from a conventional neuroleptic to an atypical antipsychotic should be performed. Antimuscarinic agents and β-blockers may be considered. However, compared with their use in patients with acute akathisia, improvement is less likely to occur.

INFORMATION FOR PATIENTS

Before initiating therapy with antipsychotic agents, clinicians should inform patients regarding the purpose of antipsychotic treatment and the potential risk of movement disorders, such as akathisia, and to document that this counseling has been performed. Informed consent is recommended by some clinicians, and should be updated yearly or when there is a change in antipsychotic therapy. The patient’s family members or caregivers can play a role in monitoring and reporting any abnormal movements. Patients and caregivers should be educated regarding the symptoms of akathisia and the importance of timely reporting, because early detection reduces the risk of irreversible abnormal movements.

TARDIVE DYSKINESIA

TDk (also referred to as tardive stereotypy) presents as delayed-onset movements manifesting as repetitive, coordinated, seemingly purposeful movements affecting the orofacial area (e.g., lips, tongue, mouth). TDk does not present as parkinsonism-based resting tremor. Many patients with TDk develop a combination of movement disorders, and the presence of multiple movement disorders should alert the clinician to the possibility of DIMDs.

CAUSATIVE AGENTS

TDk is a persistent DIMD that develops after at least 1 month of treatment with DRBAs. Agents implicated in TDk are listed in **Table 12-8**.[9-13,23,65] The term *tardive dyskinesias* emphasizes the delayed or tardive onset of choreoathetoid, stereotypic movements.

Table 12-8 Agents Implicated in Drug-Induced Tardive Dyskinesia

Drug	Incidence	Level of Evidence[a]
ANTIEMETICS/GASTRIC MOTILITY AGENTS		
Metoclopramide[23]	12–40%	B
Prochlorperazine[23]	NK	C
PSYCHOTROPICS		
Amoxapine[65]	NK	C
Atypical antipsychotics[9-11,13,b]	5–15%	A
Conventional neuroleptics[12,13,c]	20–30%	A

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Amisulpride, aripiprazole, asenapine, brexpiprazole, cariprazine, iloperidone, lurasidone, olanzapine, paliperidone, quetiapine, risperidone, sertindole, ziprasidone.

[c] Chlorpromazine, fluphenazine, haloperidol, mesoridazine, molindone, perphenazine, promazine, thioridazine, thiothixene, trifluoperazine, triflupromazine.

EPIDEMIOLOGY

Since the initial reports in the late 1950s and early 1960s, TDk has become one of the most recognized DIMDs.[66-68] In the early 1970s, product labeling for all antipsychotic drugs was revised to include information regarding TDk. Although symptoms may initially be mild, many patients develop progressively severe TDk, resulting in meaningful disability. In a study of antipsychotic-naive patients with first-episode schizophrenia, the incidence of persistent TDk increased with longer duration of treatment.[69] The cumulative incidence of TDk was 4.8% after 1 year, 7.2% after 2 years, and 15.6% after 4 years. Increasing antipsychotic drug dose was associated with a modestly increased risk of TDk, with each 100-mg chlorpromazine equivalent unit increase associated with a 5% increase in the risk of TDk. In the Hillside Hospital TDk study, young patients (mean age 29 years) were followed prospectively for several years.[70] The incidence of TDk associated with neuroleptic treatment was 5.3% per year, similar to that in other prospective studies.[12] The authors concluded that, at the end of 5 years, approximately one in four patients treated with neuroleptics were at risk for TDk. It is important to note that peculiar, choreiform orofacial movements were observed in patients with schizophrenia before the advent of conventional neuroleptic therapy and that dyskinesias may be an intrinsic motor feature of schizophrenia.[71] Although spontaneous dyskinesias occur, the data provide strong evidence demonstrating an increased incidence of TDk associated with neuroleptic drug exposure.

The overall incidence of TDk associated with neuroleptic drug therapy ranges from 0.5 to 70%.[72,73] This range reflects differences in diagnostic criteria, duration of follow-up, sampled population, and study design. Overall, TDk develops in approximately 20–30% of patients treated with conventional neuroleptics.[72,73] On the basis of studies in young patients, estimates of incidence suggest that TDk develops in about 5% of patients per year of neuroleptic exposure.[74] The highest incidence and prevalence of TDk appears to occur in the geropsychiatric population. In a study of elderly psychiatric patients who had never previously received neuroleptic agents, 35.4% developed TDk during neuroleptic treatment.[75] In a prospective study of previously neuroleptic-naive patients 55 years of age or older, the cumulative incidence of TDk was 25%, 34%, and 53% after 1, 2, and 3 years, respectively, of antipsychotic therapy.[76] In another study of middle-aged and elderly patients, the cumulative incidence of neuroleptic-induced TDk was 26%, 52%, and 60% after 1, 2, and 3 years, respectively.[77]

Neuroleptic-induced TDk is a class effect among the conventional neuroleptics. Although debatable, the risk appears to be similar for all agents within the class regardless of formulation (e.g., oral or depot injection). However, the risk of TDk is lower in association with atypical antipsychotics, regardless of prior neuroleptic exposure.[9-13] In one review of 11 long-term studies that were published between 1999 and 2002 (*n* >2,700 patients), the atypical antipsychotics (olanzapine, quetiapine, risperidone, ziprasidone) were associated with a mean annual incidence of new-onset TDk of 0.8% in adults, compared with 5.4% of those treated with haloperidol.[9] Despite the fact that most patients had been exposed to conventional neuroleptics prior to treatment with an atypical antipsychotic, the incidence of TDk was lower compared to that in haloperidol-treated patients. In this study, the risk of TDk associated with atypical antipsychotics was one-fifth that of conventional neuroleptics. A subsequent systematic review of 12 newer long-term studies published between 2004 and 2006 (*n* >30,000 patients) confirmed that atypical antipsychotics are associated with a significantly lower incidence of TDk as compared with conventional neuroleptics.[10]

Long-term use of antidopaminergic antiemetics or gastric-motility agents is also associated with a significant risk of TDk. In one study of 434 patients diagnosed with TDk in a movement disorders clinic, the causative agent was metoclopramide in 39.4% of patients, followed by prochlorperazine and promethazine in 11.8% and

9.4% of patients, respectively.[23] In 2009, the U.S. Food and Drug Administration issued a mandate that metoclopramide product labeling regarding TDk must be strengthened to a black box warning.

MECHANISMS

The pathophysiologic basis of drug-induced TDk remains speculative. Results from a study utilizing population pharmacokinetic analysis and D_2 receptor occupancy modeling suggests that higher trough D_2 receptor occupancy (i.e., high trough D_2 receptor blockade) is associated with greater risk of developing TDk.[78] Chronic D_2 receptor blockade results in various neurochemical sequelae including striatal dopaminergic hypersensitivity, cholinergic deficiency within the basal ganglia, dysfunction of striatonigral gamma-aminobutyric acid (GABA)-mediated neurons, maladaptive *N*-methyl-D-aspartate (NMDA)-mediated synaptic plasticity, glutamate-induced excitotoxicity, and oxidative stress.[79-84] Support for some of these hypotheses is derived from observations that antimuscarinic agents worsen TDk, whereas agents with GABAergic, antiglutamatergic, and antioxidant activity suppress TDk. Other mechanistic factors may include attenuation of nitric oxide–mediated neuromodulation in the striatum, genetic polymorphisms of dopamine, NMDA and serotonin receptor genes, and neuroleptic-induced neuronal apoptosis.[85-91] Ex vivo data from animal models of TDk suggest that presynaptic areas such as the substantia nigra are involved.[92] The most popular mechanistic hypothesis for TDk involves long-term blockade of striatal dopamine D_2 receptors resulting in receptor upregulation and hypersensitization. A postmortem study in neuroleptic-treated patients with schizophrenia was unable to detect significant differences in striatal dopamine D_1 or D_2 receptors between patients with and those without TDk.[93] However, an in vivo study using radioligand positron-emission tomography demonstrated that patients with the highest degree of dopamine D_2 receptor upregulation had severe TDk.[94] Within the striatum, GABA and glutamate are the major neurotransmitters that modulate the motor circuit. Evidence suggests that GABA deficiency enhances dyskinesia, and excess glutamate is implicated in neuronal toxicity. Given that several hypotheses are plausible, the pathophysiology of TDk most likely involves multiple mechanisms and events. A unifying hypothesis can be proposed: use of DRBAs results in increased dopamine turnover followed by excess free radical production and subsequent damage to striatal GABAergic fibers and reduced inhibitory activity on motor circuits. Concurrently, long-term blockade of dopamine receptors results in excessive glutamate activity and resultant excitotoxicity. Likewise, long-term dopamine receptor blockade results in receptor supersensitivity and persistent changes within the basal ganglia motor circuit.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Symptoms of drug-induced TDk are characterized by a combination of involuntary choreiform (rapid, jerky, nonrepetitive), athetoid (slow, sinuous, writhing), and stereotypic (rhythmic, repetitive) movements (Table 12-3). Regions of the mouth and face (i.e., oral, buccal, lingual, masticatory) are most commonly affected, followed by upper and lower limbs. Choreiform movements commonly affect the proximal muscles, whereas athetoid movements affect the distal muscles. Frequently, TDk occurs in the presence of other movement disorders such as akathisia, dystonia, or parkinsonism. The onset of drug-induced TDk is insidious, and symptoms are initially mild and often unnoticeable to patients. The vast majority of TDk cases are associated with antipsychotic treatment. Patients receiving long-term metoclopramide or phenothiazine antiemetic treatment are also at risk for TDk. Rarely, TDk may occur in association with other agents, such as antiepileptics, lithium, oral contraceptives, and SSRIs. If the offending drug is not discontinued, remission of TDk is rare. Occasionally, TDk may also occur after discontinuation of long-term DRBA treatment. This is reported most commonly in children, but in one study 34% of adult patients—with no prior evidence of TDk in whom neuroleptic therapy was withdrawn—developed emergent dyskinesia within 3 weeks.[74,95] In general, withdrawal dyskinesia improves within 3 months. Also, latent TDk may be "unmasked" during a reduction in neuroleptic dose and during a switch to an atypical antipsychotic.

When assessing a patient presenting with TDk symptoms, the clinician should keep in mind that orofacial dyskinesias can be a feature of several other conditions, including Huntington disease, hyperthyroidism, levodopa-induced dyskinesias, neuroacanthocytosis (choreoacanthocytosis), Sydenham chorea, and Wilson disease (Table 12-4). In addition, orofacial dyskinetic-like movements may be observed in edentulous individuals as well as patients with schizophrenia who are DRBA-naive.[96,97] In one large study of over 2,000 subjects, spontaneous dyskinesia was reported in 1.3% of healthy elderly individuals, 4.8% of medical geriatric inpatients, and up to 2% of neuroleptic-naive psychiatric patients.[74]

The diagnosis of drug-induced TDk is straightforward in most cases. For assessment purposes, the Abnormal Involuntary Movement Scale (AIMS) developed by the National Institute of Mental Health is commonly used, particularly in the psychiatric field.[98] The AIMS rates dyskinetic movements in seven body regions and includes assessments for global severity, functional impairment, and self-awareness of symptoms. Orofacial features include involuntary blinking, chewing and lower jaw movements, grimacing, lip puckering and smacking, tongue protrusion and twisting, and facial tic-like movements. Many patients also experience concurrent choreoathetoid or stereotypic movements of the feet, hands, limbs, trunk, head, and neck. Movements of the fingers may appear as though the patient is playing an invisible guitar or piano. Occasionally, patients exhibit pelvic rocking or “copulatory dyskinesia” and grunting or moaning due to respiratory and pharyngeal dyskinesia.[99] Factors associated with exacerbation of TDk symptoms include administration of antimuscarinics or sympathomimetic stimulants and emotional extremes. Symptoms of TDk can be suppressed for brief periods. Distraction during voluntary movements of unaffected body parts (e.g., finger-tapping test) or during performance of mental tasks (e.g., arithmetic) unmasks latent dyskinesia in other body parts. As with most dyskinesias, symptoms subside during sleep and, in mild cases, patients may be unaware of the movements.

Rabbit syndrome is a rare and peculiar EPS that involves a slow, rhythmic, vertical-only tremor of the perioral region that resembles the chewing motions of a rabbit. Rabbit syndrome is very specific to the buccal region only and differs from orofacial TDk in that tongue involvement is absent. Rabbit syndrome is associated predominantly with neuroleptics, with an incidence ranging from 2.3 to 4.4%.[100] Some clinicians consider rabbit syndrome to be a form of drug-induced parkinsonism.

RISK FACTORS

In general, if patients do not develop TDk during the initial 5 years of neuroleptic treatment, the risk of TDk developing during later years of therapy is reduced. Risk factors for the development of TDk include older age, mood disorder symptomatology, alcoholism or substance-use disorder, concomitant anticholinergic use, conventional (as opposed to atypical) neuroleptic use, daily drug dose, diabetes mellitus, duration of treatment, previous electroconvulsive treatment, female sex, history of EPS, intermittent (as opposed to continuous) neuroleptic treatment, iron deficiency, intellectual disability, and organic brain disorder (**Table 12-9**).[69,76,101-114] Older age is also a well-established risk factor. The risk of TDk is at least five times greater in elderly patients compared to that in young individuals.[115] Not only is TDk more common in the elderly, but TDk also tends to be more severe and irreversible in this age group. If multiple risk factors are present, an additive effect on risk potential is observed. For example, elderly women are very susceptible to TDk. Interestingly, diabetes has been associated as a risk factor for TDk in patients with schizophrenia.[108,109] Diabetic patients treated with metoclopramide are also at increased risk of TDk, compared with metoclopramide-treated nondiabetic patients.[116] However, although some atypical antipsychotics may induce glucose intolerance and diabetes mellitus, the overall risk of TDk remains low compared with that of conventional neuroleptics. The presence of a mood disorder has also been implicated as a risk factor for TDk, although supportive data are equivocal.[117,118]

Table 12-9 Risk Factors for Drug-Induced Tardive Dyskinesia

- Advanced age
- Alcoholism or substance abuse disorder
- Anticholinergic use
- Daily neuroleptic dose
- Diabetes mellitus
- Duration of neuroleptic treatment
- Female sex
- History of electroconvulsive therapy
- History of extrapyramidal symptoms
- Intermittent neuroleptic treatment
- Intellectual disability
- Iron deficiency
- Mood disorder
- Organic brain disorder

MORBIDITY AND MORTALITY

Once TDk develops, remission rates are low if therapy with the antipsychotic drug is continued. In one study, only 11% of patients improved over the course of 5 years with continued therapy.[119] If treatment is discontinued upon early detection, remission rates are favorable, especially in the younger population, but complete remission may require several months to years. However, discontinuation of antipsychotic therapy for the purpose of treating TDk is associated with risks, primarily psychotic decompensation. Mild cases of TDk are often associated with social impairment such as employment difficulties, social isolation, and stigma. Anxiety and stress further exacerbate symptoms. In more severe cases, functional impairment occurs. Patients experience difficulties with chewing, speaking, and swallowing. Orofacial dyskinesias may also result in dental problems, denture displacement, and damage to the soft tissues within the oral cavity. Gait abnormality associated with lower-extremity dyskinesia may result in falls and injury.

PREVENTION

Approaches to help prevent drug-induced TDk are summarized in **Table 12-10**. Primary prevention aided by knowledge and recognition of risk factors is key to minimizing the burden of TDk. The necessity for long-term therapy with DRBAs such as conventional neuroleptics, metoclopramide, and antidopaminergic antiemetics should be carefully evaluated. Standardized dose titration to avoid excessive dose escalation and the use of atypical antipsychotics, rather than conventional antipsychotics, are successful means of prevention. Other strategies include use of lowest effective DRBA dose and eliminating unnecessary, prolonged drug therapy. Although the use of intermittent antipsychotic treatment (or drug holidays), compared with continuous treatment, may seem like a logical strategy for reducing TDk risk, it is actually associated with an increased risk of TDk and higher rates of psychosis relapse and rehospitalization.[111,120] The American Psychiatric Association has published specific indications for short- and long-term antipsychotic drug treatment.[121]

Table 12-10 Approaches to Help Prevent Drug-Induced Tardive Dyskinesia

Amoxapine, metoclopramide, prochlorperazine

- Carefully evaluate the necessity for long-term administration
- Avoid unnecessary, prolonged drug therapy

Atypical antipsychotics

- Carefully evaluate the necessity for long-term administration
- Use standardized dose titration to avoid excessive dose escalation
- Use lowest effective dose

Conventional neuroleptics

- Carefully evaluate the necessity for long-term administration
- Use standardized dose titration to avoid excessive dose escalation
- Use lowest effective dose
- Consider use of atypical antipsychotic agent

MANAGEMENT

Early detection of drug-induced TDk is imperative, as remission rates are inversely correlated with duration and severity of TDk. For patients with dyskinesias induced by non-DRBAs (e.g., antiepileptics, lithium, oral contraceptives, SSRIs), abnormal movements generally reverse or improve within weeks after discontinuation of the offending drug. For neuroleptic-induced TDk, the movements may improve (generally within weeks) in up to 50% of patients after discontinuation of the causative agent. Thus, routine assessment for TDk (approximately every 3–6 months) is recommended. The most consistent predictor of improvement after discontinuation of neuroleptic therapy is younger age, with an inverse correlation between rates of remission and age.[122] Remission is less likely in patients with severe TDk and the elderly.

Evidence-based guidelines are available for the treatment of tardive syndromes (TDS), including TDk.[123,124] The American Academy of Neurology (AAN) guidelines address the following questions:

1. Is withdrawal of the dopamine receptor blocker an effective treatment for TDS?
2. Does switching from typical to atypical dopamine-blocking agents reduce TDS symptoms?
3. What is the efficacy of drugs in treating TDS?
4. Do patients with TDS benefit from chemodenervation with botulinum toxin?
5. Do patients with TDS benefit from surgical therapy?

The guidelines state that data are insufficient to support or refute discontinuation of therapy with the causative agent as treatment; however, from a clinical context, if TDk is present, it is recommended that the clinician discontinue therapy with the antipsychotic (applies only to patients who can tolerate this). Occasionally, discontinuation of an antipsychotic results in emergence or worsening of dyskinesia (i.e., withdrawal dyskinesia); however, withdrawal dyskinesias are generally self-limiting within 3 months.

The AAN guidelines note that short-term withdrawal may worsen TDk. In clinical practice, switching from a typical antipsychotic to an atypical antipsychotic often results in improvement, and is considered an appropriate approach if maintenance antipsychotic treatment is indicated. However, from an evidence-based perspective, the AAN panel found that data were insufficient to support or refute replacing a typical antipsychotic with an atypical agent to reduce TDk symptoms. The AAN panel reviewed studies involving several drugs for the treatment of TDk and found high levels of evidence to establish deutetrabenazine and valbenazine as effective treatments for TDk. Thus, if pharmacologic intervention is required, deutetrabenazine or valbenazine are recommended as first-line agents. Only moderate evidence is available to support the use of clonazepam and ginkgo biloba and weak evidence to support the use of amantadine and tetrabenazine. The AAN panel found insufficient evidence to support or refute the use of acetazolamide, α-methyldopa, aripiprazole, botulinum toxin type A, buspirone, bromocriptine, baclofen, clozapine, fluperlapine, flupenthixol, haloperidol, levetiracetam, melatonin, nifedipine, olanzapine, quetiapine, reserpine, selegiline, sertindole, sulpiride, thiamine, thiopropazate, vitamin B_6, vitamin E, yi-gan san, ziprasidone, and electroconvulsive therapy.

Management approaches for drug-induced TDk are summarized in **Table 12-11**. Of note, because anxiety often exacerbates signs and symptoms of TDk, concomitant anxiety should be treated appropriately. Treatment of rabbit syndrome involves reduction of the neuroleptic dose as much as possible and therapy with an antimuscarinic agent may be attempted. This contrasts with orofacial TDk, for which addition of an antimuscarinic agent tends to exacerbate the movements.

Table 12-11 Management of Drug-Induced Tardive Dyskinesia

- Discontinue or reduce dose of causative agent
- Discontinue concurrent antimuscarinic agents
- If due to neuroleptic, switch to an atypical antipsychotic
- Consider deutetrabenazine or valbenazine as first-line pharmacologic interventions
- Consider deep brain stimulation (globus pallidus) for medically refractory and severe cases
- Miscellaneous agents (amantadine, baclofen, botulinum toxin, branched-chain amino acids, clonazepam, donepezil, gabapentin, ginkgo biloba, levetiracetam, melatonin, ondansetron, pregabalin, thiamine, verapamil, vitamin B_6, vitamin E) may be considered if other interventions ineffective or not tolerated

INFORMATION FOR PATIENTS

Before initiating therapy with antipsychotics, clinicians should inform patients about the purpose of antipsychotic treatment and the potential risk of TDk and document that this counseling has been performed.[125] Some clinicians believe that such discussion concerning the risk of TDk should occur after the patient's acute psychiatric condition is stabilized, and at the time that treatment for longer than 3 months is considered.[126] Informed consent is recommended and should be updated yearly or when there is a change in antipsychotic medication.[127] The benefits and need for long-term treatment with antipsychotics should be discussed, and patients should be informed that long-term treatment can result in TDk, especially with the conventional neuroleptics. Patients should understand that movement disorders may also occur in association with the atypical antipsychotics, but are much less common and that early detection of any antipsychotic movement disorder is important and reduces the risk of irreversible abnormal movements. The patient's family members or caregivers can play a role in monitoring and reporting any abnormal movements.

DYSTONIA (ACUTE AND TARDIVE)

Drug-induced acute dystonia (DIAD) occurs shortly after the introduction of a dopamine-receptor blocking agent (e.g., antipsychotic agent) and occasionally after a dose increase or switch to a more potent antipsychotic agent, particularly an injectable high-potency antipsychotic drug. Dystonic reactions are variable in anatomical location and severity and are occasionally painful. The usual manifestations are orofacial dystonia, back arching, and neck extension (retrocollis). The term *tardive dystonia* is used to describe late-onset dystonia. Tardive dystonia is often indistinguishable from idiopathic torsion dystonia. However, patients with tardive dystonia may also have concomitant orobuccolingual dyskinesia.

CAUSATIVE AGENTS

Agents implicated in drug-induced dystonia are listed in **Table 12-12**.[11,13,37,128-136]

EPIDEMIOLOGY

The reported incidence of DIAD varies widely, from 2% to 94% of patients treated with conventional neuroleptics.[128-130] This variance may be attributed to the study method, the study setting (e.g., inpatient or outpatient), and the characteristics of the study population, including age, concurrent use of antimuscarinic agents, and type of neuroleptic agent. Other DRBAs (e.g., metoclopramide, prochlorperazine) are also associated with DIAD.[131,132] A prospective study of neuroleptic-treated psychiatric patients reported a prevalence of acute dystonia of 8.5% in those not receiving concurrent therapy with antimuscarinic agents.[137] The prevalence of acute dystonia was lower (2.8%) in patients concurrently taking an antimuscarinic drug. In the same study, DIAD was more commonly associated with butyrophenone antipsychotics (e.g., haloperidol) compared with phenothiazine antipsychotics (e.g., chlorpromazine). In an analysis of pooled data from nine studies, the overall incidence of antipsychotic-induced acute dystonia in patients not receiving antimuscarinic prophylaxis was 14.8%.[133] However, in patients receiving high-potency neuroleptics (e.g., haloperidol), the incidence was 51.2%. One retrospective study of 159 patients found the incidence of neuroleptic-induced dystonia to be 15.7%, while another retrospective study reported an incidence of 31% in young patients.[134,135] A prospective, 14-day study reported an incidence of acute dystonia of 33% associated with haloperidol treatment in young inpatients with psychosis not receiving concurrent therapy with antimuscarinic agents.[136]

Table 12-12 Agents Implicated in Drug-Induced Dystonia

Drug	Incidence	Level of Evidence[a]
ANTIEMETICS/GASTRIC MOTILITY AGENTS		
Metoclopramide[132]	1–5%	B
Prochlorperazine[131]	1–5%	B
PSYCHOTROPICS		
Atypical antipsychotics[11,13,37,b]	1–5%	A
Conventional neuroleptics[13,37,128-130,133-136,c]	1–50%	A

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies,

retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Amisulpride, aripiprazole, asenapine, brexpiprazole, cariprazine, iloperidone, lurasidone, olanzapine, paliperidone, quetiapine, risperidone, sertindole, ziprasidone.

[c] Chlorpromazine, fluphenazine, haloperidol, mesoridazine, molindone, perphenazine, promazine, thioridazine, thiothixene, trifluoperazine, triflupromazine.

Tardive dystonia is distinct from TDk, although the two often coexist. Tardive dystonia, originally known as dystonia tarda, is defined as an involuntary movement predominated by dystonia and associated with the use of a DRBA.[138,139] Tardive dystonia occurs in approximately 2–4% of patients treated with conventional neuroleptics.[140,141] However, the true incidence may be much greater. In one study of inpatient veterans receiving long-term neuroleptic treatment, the prevalence of tardive dystonia was 21.6%.[142]

MECHANISMS

Mechanisms of acute and tardive dystonias are unclear. Dopaminergic hypofunction within the basal ganglia with subsequent overactivity of the cholinergic system has been proposed, and this hypothesis is supported by the antidystonia activity of antimuscarinic agents. A contrasting hypothesis implicates striatal dopaminergic hyperactivity. In addition, other neurotransmitter systems such as GABA and serotonin may contribute.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

In most cases, the first signs and symptoms of DIAD generally appear within 48 hours of the initiation of drug therapy and, in virtually all cases, signs and symptoms appear within 5 days. Signs and symptoms of DIAD can also occur after an increase in the dose of the DRBA or a reduction in the dose of a concomitant antimuscarinic agent. The risk of DIAD appears to be greater in younger patients and in those receiving DRBAs via the parenteral route. Symptoms include sustained muscular contractions or spasms that result in abnormal fixed postures or positions of the jaw, neck, shoulders, trunk, and extremities (Table 12-3). The severity of symptoms and anatomical distribution varies, but the classic clinical presentation is characterized by the three Os: **o**culogyric crisis (conjugate deviation of the eyes upward or laterally), **o**pisthotonos or extensor axial dystonia (involuntary posturing in which the head, neck, and spine are arched backward), and **o**romandibular dystonia (forceful contractions of the jaw causing difficulty in opening or closing the mouth). Blepharospasm (involuntary eyelid closure), trismus (jaw-closing dystonia), laryngeal spasm, tongue protrusion, and respiratory stridor may also be present. Symptoms are usually painful and can interfere with walking, breathing, speaking, swallowing, and vision. In severe cases (e.g., laryngeal spasm), DIAD may be life-threatening. Rhabdomyolysis due to sustained muscle contraction may also occur. Acute dystonia is not only painful and frightening to the patient but the bizarre posturing may be mistaken for hysterical conversion by observers. If acute dystonia occurs in the presence of fever, generalized rigidity, altered level of consciousness, and autonomic instability, a diagnosis of neuroleptic malignant syndrome should be considered (Table 12-4). Dystonia may also resemble catatonia because of the underlying psychiatric disorder. However, in contrast to catatonic patients, those in whom dystonia develops report anxiety and discomfort and seek treatment. Because of the discomfort associated with DIAD, patients are at higher risk for medication nonadherence.

Tardive dystonia develops after months to years during treatment with a DRBA or within 3 months after discontinuation of therapy, and often coexists with TDk. Remission of tardive dystonia is uncommon. DRBAs are most commonly implicated in tardive dystonia. SSRIs have been rarely implicated.[16] In general, the diagnosis of tardive dystonia can be made based on the presence of persistent dystonia (for longer than 1 month), a documented history of DRBA use, and the absence of a general medical or neurologic condition that may account for dystonia (e.g., *DYTI* gene mutations and genetic forms of dystonia, focal lesions of the basal ganglia, stiff person syndrome). In contrast to DIAD, symptoms of tardive dystonia develop insidiously over weeks to months. Symptoms may or may not be painful and can be isolated to one body part (e.g., jaw, cervical area) or may spread to contiguous body parts (segmental dystonia) or even generalize to multiple body parts. Patients often report that anxiety and stress exacerbate symptoms transiently, resulting in daily variations of symptomatology. The clinical presentation of tardive dystonia resembles that of an idiopathic focal, segmental, or generalized dystonia. Cervical tardive dystonia resembles that of idiopathic cervical dystonia. In patients with cervical dystonia, the neck muscles contract involuntarily and sustained contractions cause abnormal head and neck posturing (**Figure 12-1**), whereas periodic muscular spasms cause jerky head movements that may resemble head tremors. The abnormal posturing may vary from mild to severe, pain may or may not be present, and a dystonic head tremor may be present. The concurrent presence of oromandibular dystonia with blepharospasm resembles Meige syndrome. Blepharospasm affects both eyelids and should not be mistaken for hemifacial spasm, which is a peripheral nerve disorder that is generally unilateral and involves twitching or myoclonic spasms affecting the eyelids, cheeks, and mouth regions. Tardive oromandibular dystonia is associated with persistent difficulty in opening or closing the mouth and affects chewing, speech, and swallowing. Bruxism may also accompany jaw-closing dystonia.

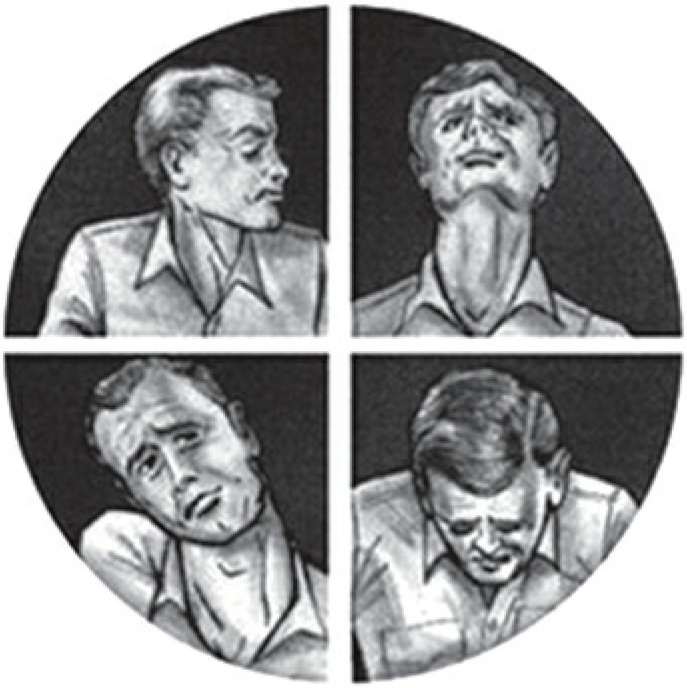

FIGURE 12-1 Cervical Dystonia

Upper left: rotational; upper right: retrocollis; lower right: anterocollis; lower left: laterocollis.

Pisa syndrome is a form of axial dystonia that is most commonly associated with neuroleptic treatment and is characterized by sustained truncal lateroflexion.[143] Drug-induced Pisa syndrome is more common in elderly patients, females, those receiving combination antipsychotics, or patients who have organic brain pathology (e.g., dementia).[144] The onset of Pisa syndrome may be acute or tardive. Treatment consists of administering antimuscarinic agents and discontinuing or reducing daily doses of the causative agent. As with tardive dystonia, Pisa syndrome responds more favorably to antimuscarinic treatment than TDk. However, unlike tardive dystonia, symptoms of Pisa syndrome generally abate after discontinuation of therapy with the causative agent. Thus, Pisa syndrome may be considered an atypical subtype of tardive dystonia. Rarely, patients with tardive dystonia may experience *status dystonicus*, a life-threatening condition associated with severe dystonic spasms resulting in rhabdomyolysis, myoglobinuria, and acute kidney injury.

In addition to idiopathic dystonia, other conditions, such as atlantoaxial rotary subluxation, conversion reaction, dopa-responsive dystonia, inherited dystonias (e.g., *DYTI*), Huntington disease, and Wilson disease must be ruled out (Table 12-4). Other conditions that cause a twisted neck, such as orthopedic or congenital problems of the neck, ophthalmologic conditions resulting in head tilt to compensate for double vision, stiff neck, arthritis, or wry neck should also be considered.

RISK FACTORS

Risk factors for the development of acute dystonia include young age (<35 years),[135] previous electroconvulsive therapy, male sex, intellectual disability, and use of high-potency neuroleptics (**Table 12-13**). As with other DIMDs, the presence of multiple risk factors confers an additive effective on risk; for example, young men are very susceptible to dystonic reactions.[137] An inverse relationship exists between the incidence of DIAD and age. In contrast to TDk, dystonia is uncommon in older patients. In one retrospective study, antipsychotic-induced acute dystonia was 15 times more common in patients under 35 years of age compared with patients older than 35 years (31% versus 2%, respectively).[135] The highest risk population is young male patients receiving high-potency neuroleptics.[145]

Table 12-13 Risk Factors for Drug-Induced Dystonia

- High-potency neuroleptics
- History of electroconvulsive therapy
- Intellectual disability
- Male sex
- Mood disorder
- Young age (<35 years)

Patients with mood disorders may be at greater risk of DIAD. In a study of 181 male patients with mania or schizophrenia treated with conventional neuroleptics, a significantly higher proportion of the manic patients (26.1%) developed acute dystonia compared to those with schizophrenia (5.9%).[146] However, subsequent studies have failed to find a significant difference in the prevalence of DIAD between manic and schizophrenic patients. In a prospective study of 31 patients, neuroleptic-induced dystonia occurred in 62.5% of patients with mania and 66.7% of those with schizophrenia.[147] In another prospective study of 83 male patients, neuroleptic-induced acute dystonia was reported in 24% of patients with mania and 15% of patients with schizophrenia.[148] Manic patients received higher peak doses of neuroleptics during the risk period for dystonia, and analysis revealed that peak neuroleptic dose and younger age were strongly related to the occurrence of dystonia.

Risk factors for tardive dystonia overlap with some of the risk factors for DIAD and include young age, male sex, and the presence of TDk. Children are considered high risk for drug-induced tardive dystonia. Duration of therapy is not consistently correlated with the risk of drug-induced tardive dystonia, which may develop after a relatively short duration of therapy or after years of treatment. In some cases, drug-induced tardive dystonia may develop following a dose increase despite a long stable period of treatment.[16]

MORBIDITY AND MORTALITY

Although drug-induced dystonia generally does not affect mortality, except in rare cases of laryngeal spasm or status dystonicus, patients are at higher risk for medication nonadherence or refusal because of the discomfort that accompanies a dystonic reaction. In moderate-to-severe cases of tardive dystonia, task-specific impairment can occur, the likelihood of which depends on the affected body part. For example, blepharospasm may impair driving abilities, anterocollis or retrocollis can interfere with maintaining an appropriate line of vision that is required for walking and other sight-directed activities, and jaw-closing dystonia can damage dentition.

PREVENTION

Approaches to help prevent drug-induced dystonia are summarized in **Table 12-14**. Primary prevention aided by knowledge and recognition of risk factors is key to minimizing the burden of drug-induced dystonia. The necessity of short- or long-term use of potentially causative DRBAs such as conventional neuroleptics, metoclopramide, and antidopaminergic antiemetics should be evaluated carefully. If indicated, the lowest effective dose should be administered, and patients should undergo regular evaluation for the emergence of dystonic posturing. Standardized dose titration to avoid excessive dose escalation and the use of atypical antipsychotics are successful means of prevention.

Table 12-14 Approaches to Help Prevent Drug-Induced Dystonia

Amoxapine, metoclopramide, prochlorperazine

- Carefully evaluate the necessity for short- or long-term therapy
- Use standardized dose titration to avoid excessive dose escalation
- Administer lowest effective dose

Atypical antipsychotics

- Carefully evaluate the necessity for short- or long-term therapy
- Use standardized dose titration to avoid excessive dose escalation
- Administer lowest effective dose
- Short-term administration of oral antimuscarinic agent (e.g., benztropine, diphenhydramine, trihexyphenidyl) may be considered for young patients receiving high-dose olanzapine, paliperidone, or risperidone

Conventional neuroleptics

- Carefully evaluate the necessity of short- or long-term therapy
- Use standardized dose titration to avoid excessive dose escalation
- Administer lowest effective dose
- Consider use of atypical antipsychotic agent
- Short-term administration of oral antimuscarinic agent (e.g., benztropine, diphenhydramine, trihexyphenidyl) may be considered, especially in young patients receiving high-potency neuroleptics

---

Several studies comparing the incidence of neuroleptic-induced acute dystonia report that administration of concurrent antimuscarinic agents (e.g., benztropine, diphenhydramine, trihexyphenidyl) reduces the overall rate of dystonia by at least twofold.[133,136,137] In patients treated with high-potency neuroleptics (e.g., haloperidol), the risk reduction is even greater (5- to 11-fold).[133,149] Because the greatest risk of neuroleptic-induced acute dystonia occurs within the first week of drug treatment, short-term administration of an oral antimuscarinic agent should be considered, especially in young patients receiving high-potency antipsychotics.[145,150,151]

The efficacy of antimuscarinic prophylaxis appears to be inversely related to age.[133] Because of reduced prophylactic efficacy and undesirable antimuscarinic adverse reactions (e.g., cognitive impairment, sedation), the use of antimuscarinic agents in elderly patients for the primary prevention of DIAD is disfavored. Although antimuscarinic agents reduce the severity of EPS, these drugs are also associated with adverse effects, such as blurred vision, cognitive impairment, constipation, dry mouth, sexual dysfunction, and urinary retention. Currently, the practice of primary prophylaxis of drug-induced dystonia with antimuscarinic agents is controversial, but appears to be reasonable in patients at high risk for dystonia (e.g., young men receiving conventional neuroleptics).

MANAGEMENT

Management approaches for drug-induced dystonia are summarized in **Table 12-15**. Acute dystonia can be relieved effectively with a short course of therapy with a potent antimuscarinic agent (e.g., benztropine, diphenhydramine) administered orally, intramuscularly, or intravenously. If drug-induced dystonia is life-threatening (e.g., stridor due to laryngospasm), intravenous administration of antimuscarinic drugs is warranted and supportive measures such as tracheostomy may be required. Benzodiazepines may be administered to relieve anxiety in conjunction with antimuscarinic therapy.

Table 12-15 Management of Drug-Induced Dystonia

Acute dystonia

- Discontinue causative agent
- Administer antimuscarinic agent

Tardive dystonia

- Discontinue or reduce dose of causative agent
- If due to neuroleptic, switch to an atypical antipsychotic
- A trial of an antimuscarinic agent may be used
- Consider tetrabenazine
- Consider botulinum toxin for focal dystonias
- A trial of muscle relaxant (e.g., baclofen) may be used
- Miscellaneous agents (amantadine, clonidine, levetiracetam, pregabalin) may be used
- Consider deep brain stimulation (globus pallidus) or pallidotomy

Symptoms of tardive dystonia also may be improved with antimuscarinic therapy. In addition, atypical antipsychotics (e.g., clozapine, quetiapine), benzodiazepines, muscle relaxants (e.g., baclofen), and dopamine-depleting drugs such as tetrabenazine are also effective. Less commonly used drugs include amantadine, β-blockers, benzodiazepines, clonidine, dantrolene, levodopa, and antiepileptics such as levetiracetam, pregabalin, tiagabine, and zonisamide.

For patients with symptoms of focal dystonia (e.g., cervical, mandibular), local injections of botulinum toxin are highly effective and are preferred because of a low incidence of systemic adverse effects. In refractory and severe cases, intrathecal baclofen and deep brain stimulation of the globus pallidus or ablative pallidotomy should be considered.[152,153]

INFORMATION FOR PATIENTS

Before initiating therapy with DRBAs, clinicians should inform patients regarding the purpose of treatment and the potential risk of dystonia and document that this counseling has been performed. If long-term treatment with a DRBA is anticipated, informed consent is recommended and should be updated yearly. Patients should also understand that early detection of any DRBA-induced movement disorder is important and reduces the risk of irreversible abnormal movements. The patient’s family members or caregivers can play a role in monitoring and reporting any abnormal movements.

PARKINSONISM

CAUSATIVE AGENTS

After idiopathic Parkinson disease, drug-induced parkinsonism (DIP) is considered the second most common form. DIP is associated with up to 15% of all cases of parkinsonism worldwide. In one study of elderly patients, 51% of newly referred cases of parkinsonism were believed to be caused by drugs.[154] Agents implicated in drug-induced parkinsonism are listed in **Table 12-16**.[6,37,155-165] The DRBAs are the most commonly implicated agents, and are responsible for 70–80% of DIP cases worldwide. Valproate is a common cause of DIP.[159] Valproate-induced parkinsonism is often characterized by concurrent cognitive and hearing impairment and is underreported because of its insidious onset. The SSRIs are rarely associated with DIP, although SSRI-induced tremor is common.

EPIDEMIOLOGY

In patients treated with conventional neuroleptics, the prevalence of DIP ranges from 20% to 66%.[6,155,156] The prevalence of parkinsonism associated with atypical antipsychotics is much lower. In one study, the prevalence of parkinsonian rigidity associated with clozapine, risperidone, and conventional neuroleptics was 4.9%, 17.4%, and 35.7%, respectively.[37]

Table 12-16 Agents Implicated in Drug-Induced Parkinsonism

Drug	Incidence	Level of Evidence[a]
ANTIEMETICS/GASTRIC MOTILITY AGENTS		
Metoclopramide[157]	1–5%	B
Prochlorperazine[158]	1–5%	B
ANTIEPILEPTICS		
Valproate[159]	5%	B
CARDIOVASCULAR DRUGS		
Methyldopa[159]	NK	C
Reserpine[161]	NK	C
PSYCHOTROPICS		
Amoxapine[162]	NK	C
Atypical antipsychotics[37,b]	5–20%	A
Conventional neuroleptics[6,155,156,c]	20–60%	A
VESTIBULAR SEDATIVES		
Cinnarizine[163,d]	30%	B
Flunarizine[163,d]	30%	B
MISCELLANEOUS		
Tetrabenazine[164,165]	15%	A

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Amisulpride, aripiprazole, asenapine, brexpiprazole, cariprazine, iloperidone, lurasidone, olanzapine, paliperidone, quetiapine, risperidone, sertindole, ziprasidone.

[c] Chlorpromazine, fluphenazine, haloperidol, mesoridazine, molindone, perphenazine, promazine, thioridazine, thiothixene, trifluoperazine, triflupromazine.

Table 12-17 Mechanisms of Drug-Induced Parkinsonism

Drug	Mechanism
Amoxapine Atypical antipsychotics[a] Cinnarizine Conventional neuroleptics[b] Flunarizine Metoclopramide Prochlorperazine	Blockade of striatal dopamine-2 receptors
Methyldopa Reserpine Tetrabenazine	Neuronal dopamine depletion
Valproate	Unknown

[a] Amisulpride, aripiprazole, asenapine, brexpiprazole, cariprazine, iloperidone, lurasidone, olanzapine, paliperidone, quetiapine, risperidone, sertindole, ziprasidone.

[b] Chlorpromazine, fluphenazine, haloperidol, mesoridazine, molindone, perphenazine, promazine, thioridazine, thiothixene, trifluoperazine, triflupromazine.

MECHANISMS

The mechanism of DRBA-induced parkinsonism involves occupancy and blockade of striatal dopamine receptors (**Table 12-17**).[166-169] Relative to the conventional neuroleptics, the affinity of atypical antipsychotic agents for striatal dopaminergic receptors is lower, which helps to explain the dose-dependent incidence of parkinsonism induced by conventional neuroleptics and some of the atypical antipsychotics, such as olanzapine, paliperidone, and risperidone. However, receptor affinity and dissociation also play a role, and rapid dissociation from dopamine D_2 receptors (i.e., “fast-off-D_2”) plays a role in mitigating EPS risk.[170,171] According to the fast-off-D_2 model, atypical antipsychotics bind loosely to dopamine D_2 receptors, resulting in a short duration of binding, which is sufficient to produce antipsychotic activity without inducing EPS. Conventional neuroleptics bind tightly to dopamine D_2 receptors and thus produce antipsychotic activity, but with an increased risk of inducing EPS. Furthermore, among the atypical antipsychotics, fast-off-D_2 occurs more readily with low-potency agents compared with high-potency agents. For example, EPS is rarely associated with clozapine (an agent that requires higher doses for efficacy) compared with risperidone (an agent that requires lower doses). In addition, the atypical antipsychotics also block 5-HT_{2A} receptors that project to the presynaptic aspect of nigrostriatal dopamine neurons. Because activation of 5-HT_{2A} receptors inhibits dopamine release, blockade of these 5-HT_{2A} receptors enhances dopamine release sufficiently to mitigate the risk of EPS.

In addition to the DRBAs (e.g., antipsychotics, metoclopramide), drugs that deplete presynaptic dopamine (e.g., reserpine, tetrabenazine) or act as dopamine "false transmitters" (e.g., α-methyldopa) can also induce parkinsonism.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

In general, the clinical features of DIP are indistinguishable from those of idiopathic parkinsonism and include at least two of the following: tremor (rest or postural), rigidity, and bradykinesia (Table 12-3). In the absence of an accurate drug history, DIP can be easily mistaken for idiopathic Parkinson disease. Recognition of DIP may be difficult, as symptoms such as diminished facial expression, reduced energy and motivation, and bradykinesia can mimic negative symptoms of schizophrenia as well as psychomotor retardation associated with depressive disorders (Table 12-4). Tremor is often the most visible feature of DIP, but the presence of tremor in the absence of bradykinesia or rigidity is not parkinsonism. Symptoms of bradykinesia and rigidity often result in masked facies, shuffling gait, slowness of movement, and difficulty with daily tasks (e.g., walking, dressing, eating, grooming, writing). Some investigators define classic DIP as characterized by symmetrical distribution of symptoms, the additional presence of a chin or jaw tremor, and greater postural instability (balance problems and falling) upon initial presentation.[172,173] Single-photon emission computed tomography using a dopamine transporter ligand (e.g., ^{123}I-ioflupane) can be used to differentiate DIP from idiopathic Parkinson disease; results of this test should be normal in patients with DIP. In the majority of cases, DIP develops within 3 months of initiating therapy with the causative agent or, in some cases, after a dose increase, and is reversible upon drug discontinuation. Occasionally, the onset may be acute. Generally, DIP remits (over a period of several months) following discontinuation of therapy. However, some patients may have persistent DIP. The Simpson-Angus Scale is a 10-item rating scale that has been used widely for assessment of DIP in both clinical practice and research settings.[174] The scale consists of one item measuring gait (hypokinesia), six items measuring rigidity, and three items measuring glabella tap, tremor, and salivation, respectively.

RISK FACTORS

Risk factors for the development of DRBA-induced parkinsonism include vulnerability to EPS (e.g., older age, dementia, or pre-existing parkinsonism), female sex, and use of central DRBAs (e.g., metoclopramide, phenothiazine, and butyrophenone antipsychotics) (**Table 12-18**). Patients with acquired immunodeficiency syndrome (AIDS) appear to be very susceptible to DIP. In one study, the likelihood of EPS was 2.4 times higher among patients with AIDS as compared with patients with psychiatric disorders who did not have AIDS.[175]

Table 12-18 Risk Factors for Drug-Induced Parkinsonism

- Acquired immunodeficiency syndrome
- Advanced age
- Dementia
- Female sex
- Underlying Parkinson disease

MORBIDITY AND MORTALITY

Discontinuation of therapy with the offending agent often results in some improvement of parkinsonian features within 2 weeks. However, complete improvement is often not achieved for months or up to a year. In a subset of patients, features of parkinsonism remain indefinitely, despite discontinuation of therapy with the offending agent. Of the motor features, tremor typically confers the smallest degree of impairment of activities of daily living, as compared with bradykinesia.

PREVENTION

Approaches to help prevent drug-induced parkinsonism are summarized in **Table 12-19**. Primary prevention aided by knowledge and recognition of risk factors is key to minimizing the burden of DIP. The necessity for long-term use of potentially causative DRBAs such as conventional neuroleptics, metoclopramide, and antidopaminergic antiemetics should be carefully evaluated. If indicated, the lowest effective dose should be used and patients should undergo regular evaluation for emergence of symptoms of parkinsonism. Standardized dose titration to avoid excessive dose escalation and the use of atypical antipsychotics are successful means of prevention. In practice, some clinicians routinely use antimuscarinic agents for primary prophylaxis of DIP, but this approach is controversial, especially for elderly patients.

Table 12-19 Approaches to Help Prevent Drug-Induced Parkinsonism

Amoxapine, atypical antipsychotics, cinnarizine, flunarizine, metoclopramide, prochlorperazine, tetrabenazine

- Carefully evaluate the necessity for long-term therapy
- Use standardized dose titration to avoid excessive dose escalation
- Administer the lowest effective dose

Conventional neuroleptics

- Carefully evaluate the necessity for long-term therapy
- Use standardized dose titration to avoid excessive dose escalation
- Administer the lowest effective dose
- Consider use of atypical antipsychotics
- Initiation of therapy with antimuscarinic agent for primary prevention is controversial, especially for the elderly

Methyldopa, reserpine, valproate

- No known means of prevention

MANAGEMENT

Strategies for the management of DIP include discontinuation of therapy with the causative agent, reducing the dose of the offending drug, changing therapy from a conventional neuroleptic to an atypical antipsychotic agent, and the use of antiparkinsonism drugs such as amantadine, antimuscarinics, carbidopa–levodopa, and dopamine agonists (**Table 12-20**). For symptom management, dopamine agonists and carbidopa–levodopa are effective, but a severe neuroleptic-induced parkinsonian tremor may be resistant. Alternatively, antimuscarinic agents can be used and are better tolerated in younger patients. Amantadine is another alternative and is better tolerated than anticholinergic drugs in the elderly.

Table 12-20 Management of Drug-Induced Parkinsonism

- Discontinue or reduce dose of causative agent
- If due to neuroleptic, switch to an atypical antipsychotic
- Consider a trial of antimuscarinic, amantadine, dopamine agonist, or levodopa

INFORMATION FOR PATIENTS

Before initiating therapy with DRBAs, clinicians should inform patients regarding purpose of treatment and the potential risk of DIP and document that this counseling has been performed. If long-term treatment with a DRBA is anticipated, informed consent is recommended and should be updated yearly. Patients should also understand that early detection of any DRBA-induced movement disorder is important and reduces the risk of irreversible abnormal movements. The patient's family members or caregivers can play a role in monitoring and reporting any abnormal movements.

CHAPTER 13

Peripheral Neuropathy

Dennis Parker, Jr.

Peripheral neuropathy is defined as a dysfunction or lesion in the peripheral nervous system that is usually characterized by pain, abnormal sensory symptoms, or both.[1] Although this syndrome is most commonly a complication of chronic illnesses such as diabetes mellitus, alcoholism, or human immunodeficiency virus (HIV) infection, it may also be drug-induced.

CAUSATIVE AGENTS

Many drugs have been associated with peripheral neuropathy. The most common agents that have been implicated include antineoplastic and antiretroviral drugs. Drugs known to cause peripheral neuropathy are listed in **Table 13-1**.[2-93]

EPIDEMIOLOGY

The precise incidence of drug-induced peripheral neuropathy is unknown. Despite few epidemiologic data, it seems likely that the overall incidence of drug-induced peripheral neuropathy is low, and varies depending on the specific medication, its duration of use and dose, and patient-specific factors.[94] The risk of peripheral neuropathy is notably high in association with certain drug classes. Cancer chemotherapy agents (platinum derivatives, taxanes, vinca alkaloids) and antiretroviral drugs (nucleoside reverse-transcriptase inhibitors) are commonly associated with peripheral neuropathy. The incidence of peripheral neuropathy has been reported to be as high as 85–100% in patients receiving higher doses of cisplatin or oxaliplatin and 30–80% in patients with HIV who receive zalcitabine.[25,34,95-97] Most other associations of peripheral neuropathy with drugs are limited to case reports or small case series. Some population-based cohort studies examining the risk of peripheral neuropathy associated with lipid-lowering agents such as statins have been published. One group conducted a study in 166 patients and reported a 4- to 14-fold increased risk of idiopathic polyneuropathy in those on long-term (median 2.8 years) therapy with statins.[55] A subsequent analysis of four cohort trials estimated the incidence of neuropathy associated with statin use to be low (12 per 100,000 person-years).[98] More recent data suggest a clear association between long-term statin exposure and risk of peripheral neuropathy.

Table 13-1 Agents Implicated in Drug-Induced Peripheral Neuropathy

Drug	Incidence	Level of Evidence[a]
ANTI-INFECTIVES		
Chloramphenicol[2,3]	NK	C
Chloroquine[4,5]	NK	C
Ciprofloxacin[6]	NK	C
Dapsone[7,8]	NK	C
Didanosine[9,10]	Up to 23%	B
Ethambutol[11,12]	NK	C
Isoniazid[13-15]	NK	C
Lamivudine[16]	NK	C
Levofloxacin[6]	NK	C
Linezolid[17]	NK	C
Lomefloxacin[6]	NK	C
Mefloquine[18]	NK	C
Metronidazole[19-21]	NK	C
Nitrofurantoin[22]	NK	C

Ofloxacin[6]	NK	C
Podophyllin[23]	NK	C
Stavudine[24]	6–31%	A
Trovafloxacin[6]	NK	C
Zalcitabine[25-27]	>30%	A
ANTINEOPLASTICS		
Fluorouracil[28]	1%	C
Bortezomib[29]	30–47%	A
Capecitabine[30]	NK	C
Carboplatin[31-33]	15–85%	A
Chlorambucil[31]	NK	C
Cisplatin[31,34,35]	15–85%	A
Cytarabine[36]	NK	C
Docetaxel[37,38]	50%	A
Etoposide[39]	NK	C
Ifosfamide[40]	NK	C
Oxaliplatin[41-43]	85%	A
Paclitaxel[44-46]	50%	A
Procarbazine[47]	10–20%	C
Suramin[48]	NK	C
Thalidomide[49,50,51]	50%	A
Vincristine[46,52]	50%	A
CARDIOVASCULAR DRUGS		
Amiodarone[53,54]	NK	C
Atorvastatin[55]	NK	C
Clofibrate[56]	NK	C
Disopyramide[57]	NK	C
Enalapril[58,59]	NK	C
Hydralazine[60,61]	NK	C
Indomethacin[62]	NK	C
Pravastatin[55]	NK	C
Propafenone[63]	NK	C

Rosuvastatin[55]	NK	C
Simvastatin[55]	NK	C
MISCELLANEOUS		
Acetazolamide[64,65]	NK	C
Alcohol[66]	NK	C
Allopurinol[67]	NK	C
Colchicine[68]	NK	C
Cyclosporine[69,70]	NK	C
Disulfiram[71-74]	NK	C
Gold salts[75-77]	NK	C
Interferons alfa 2a and 2b[78-80]	NK	C
Infliximab[81]	NK	C
Leflunomide[82,83]	3–10%	B
Lithium[84]	NK	C
Nitrous oxide[85]	NK	C
Penicillamine[86]	NK	C
Phenelzine[87,88]	NK	C
Phenytoin[89,90]	NK	C
Pyridoxine[91]	NK	C
Sulfasalazine[92]	NK	C
Tacrolimus[93]	NK	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

MECHANISMS

Peripheral neuropathy is associated with damage to the peripheral nervous system, namely the dorsal-root ganglia and dorsal roots. The cell bodies of sensory neurons lie in the dorsal-root ganglia, which give rise to the dorsal roots (axons). It is postulated that drugs may affect the peripheral nervous system selectively because these anatomical structures have a somewhat porous blood–nerve barrier, thus allowing access of harmful toxins.[94,99] Others have pointed out that increased access to sensory neurons alone could not explain susceptibility, as autonomic neurons lack a blood–brain barrier and autonomic dysfunction is commonly absent in patients with drug-induced peripheral neuropathy.[44]

Although mechanisms by which drugs induce peripheral neuropathy have not been fully elucidated, the general pathogenesis of drug-induced peripheral neuropathy primarily involves axonal or cell-body degeneration, demyelination, or both. Axonal degeneration is often associated with the "dying back" phenomenon, in which the most distal portion of the axon degenerates and the myelin sheath begins to break down more proximally toward the cell body.[100]

For some drugs with well-established associations with peripheral neuropathy, several cellular pathways have been identified using in vitro methods and animal models (**Table 13-2**).[101-104] In some cases individual agents are associated with multiple neurotoxic mechanisms.[104] The therapeutic mechanism of action of some drugs is also associated with detrimental consequences to sensory neurons. Nucleoside reverse-transcriptase inhibitors cause peripheral neuropathy by depleting mitochondrial deoxyribonucleic acid (DNA) in neurons. These agents exert a therapeutic effect on HIV reverse-transcriptase DNA but are also substrates for gamma DNA polymerase, which is responsible for replication of neuronal mitochondrial DNA.[105] Vinca alkaloids destroy cancer cells by binding with tubulin to prevent microtubular formation, which disrupts mitosis. Axonal transport is dependent on microtubular function. Dysfunction of axoplasmic transport has been demonstrated in animal models.[35,106,107] Other important mechanisms for chemotherapy associated neuropathy have been identified, including the release of proinflammatory mediators, enhanced oxidative stress, disruption of voltage-gated ion channels, and neuronal apoptosis.[108] Other drugs may affect important mediators of metabolic function. Isoniazid inhibits phosphorylation of pyridoxine, which causes neuronal cellular dysfunction.[109] Paradoxically, pyridoxine overdose is also associated with peripheral neuropathy.[110]

Table 13-2 Mechanisms of Drug-Induced Peripheral Neuropathy

Drug	Mechanism
Nucleoside reverse-transcriptase inhibitors	Depletion of mitochondrial DNA in neurons
Taxanes and vinca alkaloids	Disruption of neuronal axonal transport
Platinum compounds	Cross-linkage of DNA strands to impair cell division; demyelination and axonal swelling in dorsal-root ganglia
Oxaliplatin (acute)	Interaction with ion channels in dorsal root to enhance Na++ transmission; chelation of Ca++ ions. Overall shift to more negative membrane potential
Thalidomide	Down regulation of the production of tumor necrosis factor α and

Bortezomib	inhibition of nuclear factor-κβ leading to reduced nerve growth factor–mediated neuron survival
Isoniazid	Inhibition of phosphorylation of pyridoxine, which leads to neuronal cellular dysfunction
Linezolid	May disrupt neuronal mitochondrial protein synthesis
Statins	Inhibition of HMG-CoA reductase leading to reduced cholesterol synthesis, which is necessary for maintenance of cell-membrane integrity in neurons

DNA = deoxyribonucleic acid, HMG-CoA = 3-hydroxy-3-methyl-glutaryl-coenzyme A.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

A wide spectrum of clinical features can be observed in patients with drug-induced peripheral neuropathy (**Table 13-3**). Symptoms are most often sensory or sensorimotor in nature, and patients present in a similar fashion to those afflicted with peripheral neuropathy due to other causes. The clinical syndrome may be dependent on many factors. Drugs that affect large myelinated axons (e.g., paclitaxel) cause disturbances of proprioception, vibration, and light touch. Others, such as cisplatin, are more selective for small fibers and may cause pain or abnormal temperature sensation.[25,34] Patients with sensorimotor neuropathy present with sensory as well as motor symptoms such as weakness or muscle cramps. The onset and severity of these symptoms vary. Most commonly, neurotoxicity is a dose-related phenomenon that occurs after prolonged, cumulative exposure to the offending agent (weeks to months). In some instances, however, acute symptoms may appear after a single exposure to the drug (e.g., oxaliplatin, paclitaxel).[34] Oxaliplatin induces a unique form of acute neuropathy in a majority of patients, who experience paresthesias in the extremities. Rarely, pharyngolaryngeal dysesthesia may occur, which is manifested as unusual sensations in the mouth or throat and difficulty in swallowing or breathing.[33] Symptoms may begin during the infusion of the drug or shortly thereafter. This syndrome usually resolves spontaneously within days of onset but can recur with subsequent infusions.

Table 13-3 Signs and Symptoms Associated with Drug-Induced Peripheral Neuropathy[a]

- Orthostatic hypotension (autonomic neuropathy)
- Reduced sensation (vibration, pinprick)
- Reduced (abnormal) reflexes in affected area
- Reduced nerve action potential amplitude (nerve conduction studies)
- Paresthesias
- Burning sensations

- Shock-like sensations
- Decreased sensations or numbness
- Shooting or stabbing pain
- Radiating pain
- Ataxia

---

[a] Symptoms are typically distal and symmetrical in nature.

Neurotoxic antiretroviral drugs may provoke a syndrome known as “coasting,” in which symptoms begin to occur some time after the drug has been discontinued.[111,112] Symptoms may actually worsen for a period of 1–2 months after the offending agent is discontinued. Some drugs known to cause peripheral neuropathy also cause autonomic or optic neuropathies or purely motor abnormalities.

Identifying the cause of peripheral neuropathy can be challenging. Even with extensive investigation, the exact cause is often elusive. In a small study, nearly 50% of cases of sensory neuropathy were categorized as idiopathic.[99] It follows, therefore, that distinguishing drug-induced peripheral neuropathy from nondrug causes can be a daunting task. Drug-induced peripheral neuropathy is often a diagnosis of exclusion, because numerous causes of peripheral neuropathy exist, many of which present in a fashion similar to those that are drug-related. A careful medical history and physical examination are important for diagnosis, and additional tests may be required to establish the most likely cause.

It is important that clinicians inquire specifically about the frequency, quality, and duration of symptoms of peripheral neuropathy. Knowledge of the onset and duration of symptoms is particularly helpful in discerning the etiology of neuropathy, because drug-induced peripheral neuropathy usually presents as a subacute process over several weeks to months. The patient’s medical history should be assessed for trauma, infectious diseases (especially HIV), conditions such as diabetes mellitus, kidney or liver disease, cancer, and family history of neuropathy. The patient should also be evaluated for alcohol abuse and for exposure to other potentially neurotoxic chemicals or medications.

On physical examination, drug-induced peripheral neuropathy is usually distal, symmetrical, and sensorimotor in nature. The neurologic exam may reveal a reduced sensation on pinprick as well as reduced vibratory sense bilaterally in the extremities.[113] The reduction in sensation may result in subsequent formation of ulcers. In some cases, hyperesthesia or allodynia may be present. Weakness or clumsiness may be observed in patients with motor involvement secondary to neuropathy. Deep tendon reflexes may be absent or reduced in affected areas.

Grading scales for neuropathy—particularly chemotherapy-induced peripheral neuropathy (CIPN)—are widely used by clinicians to assess the scope and severity of drug-induced peripheral neuropathy as a component of patient monitoring and during clinical trials. The most widely used scales are the National Cancer Institute of Canada Common Toxicity, Eastern Cooperative Oncology Group, and World Health Organization grading scales. These scales generally classify patients from 0 (no symptoms) to up to 4 or 5 (severe, disabling symptoms). Although these tools are helpful, a substantial amount of variability exists between examiners using these scales because of the subjective nature of some classification schemes. More in-depth descriptions of these scales are published elsewhere.[114-116]

Nerve-conduction studies (NCS) and electromyography (EMG) are the primary tools used in electrodiagnostic studies. These tests are usually performed in concert to identify disorders occurring in the nerves, muscle, or both. EMG is used to study the electrical activity of muscles, whereas NCS assess motor and sensory function of the nerves. EMG and NCS are performed by generating a small electrical current via a stimulator placed on the skin along a nerve. Electrical activity is recorded—using either surface electrodes (i.e., NCS) or needle electrodes inserted into muscles (i.e., EMG)—and is visualized as waveforms on a monitor. The amplitude of the waveform estimates the amount of electrically active tissue. Conduction velocity is a measurement of how quickly neurons are propagating impulses. Both amplitude and conduction velocity data generated during NCS can aid in the determination of the level of peripheral nerve disease (i.e., demyelination versus axonal degeneration). In general, axonal destruction produces a reduction in amplitude. This represents the most common consequence of neuropathy induced by medications. In contrast, demyelination is associated with a reduction in conduction velocity, which may occur in patients who receive amiodarone. Although electrophysiologic testing may be useful in identifying the presence of peripheral neuropathy in some patients, many investigators have found a poor correlation between performance on NCS and clinical symptoms of the disease.[117,118] Furthermore, it has yet to be shown that NCS are useful in predicting the future development of peripheral neuropathy in patients receiving potentially neurotoxic drugs. Mileshkin et al.[118] studied the utility of serial NCS in 75 patients receiving thalidomide for relapsed or refractory multiple myeloma in an effort to identify those at risk for developing peripheral neuropathy. Electrophysiologic monitoring was found to be no better than clinical assessment for identifying patients at risk for thalidomide-induced peripheral neuropathy. Therefore, the utility of the routine use of NCS to identify patients at risk for peripheral neuropathy remains unclear.

Table 13-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Peripheral Neuropathy

- Immune-related disorders
    - Guillain-Barré syndrome
    - Sjögren syndrome
    - Chronic inflammatory demyelinating polyradiculoneuropathy
- Infectious diseases
    - Human immunodeficiency virus

    - Herpes simplex
- Metabolic/systemic diseases
    - Nutritional deficiency
    - Diabetic neuropathy
    - Hypothyroidism
- Traumatic injury
- Hereditary sensory neuropathies
- Idiopathic sensory neuropathy
- Paraneoplastic neuropathy

Conditions to consider in the differential diagnosis of drug-induced peripheral neuropathy are listed in **Table 13-4**. A wide variety of systemic diseases, particularly diabetes mellitus, kidney disease, and thyroid disease may play a role in producing neuropathy. Therefore, complete blood count, fasting blood glucose, blood urea nitrogen and creatinine, and thyroid-stimulating hormone concentrations should be evaluated. Serum vitamin B_{12} concentrations can also be easily obtained and should be included in the patient evaluation. A serum concentration of 100 pg/mL or less with symptoms is usually indicative of vitamin B_{12} deficiency. Malignancy has also been associated with peripheral neuropathy, which is a common presenting feature in patients with small-cell lung cancer.[99] In these patients, symptoms of sensory neuropathy often occur rather abruptly, a presentation that differs from the more common subacute presentation of drug-induced peripheral neuropathy. Therefore, a routine cancer evaluation including chest radiography and measurement of anti-Hu antibodies should be performed in any patient presenting with acute symptoms of neuropathy. Cerebrospinal fluid evaluation may be useful in screening patients for immune-related causes such as Guillain-Barré syndrome and chronic inflammatory demyelinating polyradiculoneuropathy, as elevated plasma protein concentrations may be found in patients with these illnesses. Nerve biopsy, which involves removing and examining nerve tissue, is generally poorly tolerated and can cause complications of neuropathy. Therefore, this technique is reserved for patients for whom the diagnosis of neuropathy cannot be determined by other means.[99,100,119]

RISK FACTORS

Risk factors for the development of drug-induced peripheral neuropathy are listed in **Table 13-5**. For the most part, cumulative drug exposure increases the risk of peripheral neuropathy, and repeated exposure to an agent that has caused peripheral neuropathy further increases the risk. However, evidence indicates that some patients can be safely rechallenged with cisplatin.[120] For many anticancer drugs, the risk of neurotoxicity appears to be related to both the amount of drug administered in each individual dose and the cumulative dose. Postma et al.[121] studied the effect of dose-dependent neurotoxicity in 227 patients with cancer receiving paclitaxel in doses ranging from 135 to 300 mg/m^2 every 3 weeks. The incidence of neuropathy was higher in patients who had received both a higher cumulative dose and a higher dose per cycle. Similar effects have been noted in patients receiving high doses of oxaliplatin, cisplatin, and vincristine. Therefore, it appears that both total drug exposure and dose intensity can influence the risk of chemotherapy-induced neuropathy.[122,123]

Table 13-5 Risk Factors for Drug-Induced Peripheral Neuropathy

- Prolonged duration of therapy with potentially causative agents
- High drug doses
- Human immunodeficiency virus
- Diabetes mellitus
- Hypothyroidism
- Pre-existing neuropathy
- Concomitant administration of multiple agents known to cause neuropathy
- Possible genetic predisposition
- Impaired hepatic or renal drug metabolism/elimination
- Rapid infusion of some antitumor agents

Concomitant administration of neurotoxic HIV medications may result in a substantial increase in the risk of peripheral neuropathy.[124] In addition, HIV infection itself is associated with peripheral neuropathy, and the incidence is higher in patients with a high viral load or low CD4 count.[125] Genetic factors appear to play a role in the development of drug-induced peripheral neuropathy in many patients. The risk of peripheral neuropathy associated with isoniazid and hydralazine may be higher in patients with reduced activity of hepatic *N*-acetyltransferase (i.e., “slow acetylators”). Roughly 50% of Caucasians and African-Americans are slow acetylators. Acetylation status may also be of importance with respect to thalidomide-induced peripheral neuropathy.[117] One study in patients with HIV receiving combination antiretroviral therapy found that genetic polymorphisms in iron-transport genes were associated with a higher risk of sensory neuropathy.[125] Several genetic polymorphisms are postulated to modulate the risk of chemotherapy-induced neuropathy with drugs such as bortezomib, vincristine, and platinum derivatives. However, clinical findings are inconsistent and thus the benefit of pharmacogenomic testing in individual patients remains to be determined.[126-128]

Diabetes mellitus, alcohol abuse, and nutritional deficiencies all pose a significant risk for the development of peripheral neuropathy. Patients with severe hepatic disease are at an increased risk of neuropathy. In many cases, thiamine deficiency secondary to alcohol abuse has been implicated as a potential mechanism of nerve damage, although some data suggest that toxicity occurs in the absence of chronic alcoholism. Patients with chronic kidney disease are also at risk of vitamin deficiencies. Furthermore, uremia can expose patients with end-stage kidney disease to a variety of toxic substances (phenols, myoinositol) that have been associated with neurotoxicity. Therefore, caution must be used when prescribing potentially neurotoxic medications to these patients who are at a higher risk for drug-induced peripheral neuropathy.[129-133]

MORBIDITY AND MORTALITY

Drug-induced peripheral neuropathy can produce symptoms ranging from mild, annoying paresthesias to painful sensations that can exert a significant impact on the quality of life. Some drugs can induce autonomic neuropathy, which can lead to troublesome symptoms including orthostatic hypotension, severe constipation, and impotence.[134] Rarely, anti-tumor necrosis factor-α therapy has been associated with symptoms similar to multifocal motor neuropathy, which is characterized by severe muscle weakness.[135] Fortunately, the majority of patients with drug-induced neuropathy demonstrate at least partial improvement in symptoms following discontinuation of the offending agent, and many patients experience complete recovery.[35] The coasting phenomenon may occur, however, in some patients after the drug is discontinued. The time to improvement in symptoms after discontinuing some agents may take as long as several months to years. Resolution is dependent on underlying mechanisms and the duration and extent of neuronal damage. Recovery from axonal damage may be prolonged, whereas recovery from a demyelinating process may be more rapid.[119]

PREVENTION

The most effective means for preventing drug-induced peripheral neuropathy is avoidance of use of drugs known to cause the disease in patients with known risk factors (**Table 13-6**). Clinicians should be cognizant of the neurotoxic potential of medications so that patients can be screened for risk factors before initiation of therapy. Medications with a potential to cause peripheral neuropathy should be administered at the smallest effective dose for the shortest possible duration, and doses should be adjusted appropriately in patients with kidney or liver disease.[119] Drugs that can potentially induce vitamin B deficiency, such as isoniazid, should be coadministered with pyridoxine 25–50 mg/day.

Table 13-6 Approaches to Help Prevent Drug-Induced

Peripheral Neuropathy

- Limit/monitor for potential predisposing risk factors
  - o Use lowest dose possible to achieve desired effect
  - o Monitor blood urea nitrogen and serum creatinine concentration in patients taking renally eliminated drugs; adjust dose appropriately if kidney disease occurs
  - o Monitor liver function in patients taking hepatically eliminated agents; adjust dose if hepatic impairment occurs
- Monitor for signs/symptoms of peripheral neuropathy
- Educate patients about potential symptoms of neuropathy
- Routine clinical neurologic assessment
- Electrophysiologic testing may be useful (NCS, EMG)
- Drugs
  - o Routine pyridoxine therapy in patients receiving drugs that may induce vitamin B_{12} deficiency (e.g., isoniazid)

EMG = electromyography, NCS = nerve conduction studies.

Although CIPN is predictable and well established, pharmacologic measures to prevent this complication have generally been disappointing. Although no drugs are currently recommended for the prevention or treatment of CIPN, several strategies have been used to attempt to reduce the risk of this complication (**Table 13-7**).[136] Many agents (amifostine, vitamin E, glutathione, adrenocorticotropic hormone, acetyl-L-carnitine) have been found to be initially effective in mitigating pain in animal models or small trials. Unfortunately, all of these compounds were later found ineffective in large randomized studies.[114,137-143] A recent trial evaluating acetyl-L-carnitine for the prevention of neuropathy in bortezomib-treated patients with multiple myeloma found that the intervention was not only ineffective, but acetyl-L-carnitine may have attenuated the effectiveness of the chemotherapy regimen against myeloma cells.[143]

Acute neuropathy associated with oxaliplatin occurs commonly. Symptoms may be triggered by exposure to cold, and consequently patients should be instructed to avoid extremes in temperatures and cold beverages. Long-term exposure can also cause cumulative toxicity similar to that associated with other platinum compounds. It is postulated that neurotoxicity after oxaliplatin exposure is the result of hyperexcitability due an interaction with ion channels (channelopathy) that results in a relative increase of sodium current. This is likely a result of calcium ion chelation by oxaliplatin or its oxalate metabolite.[104] Some data suggest that prophylactic administration of the sodium-channel blocker carbamazepine or oxcarbazepine may prevent acute oxaliplatin neurotoxicity. Results of unblinded trials showed that neuropathy was less severe in patients receiving oxaliplatin therapy who also received carbamazepine or oxcarbazepine.[144,145] Conversely, in another study, prophylactic carbamazepine administration failed to confer a significant benefit on electrophysiologic studies or symptomatic relief.[146] Much attention has been devoted to the use of calcium and magnesium to prevent chelation and reduce oxaliplatin-induced excitation, based on theoretical beneficial effects. Many clinicians advocated the use of prophylactic infusions of calcium and magnesium salts, particularly after the publication of a retrospective study of 161 patients with colorectal cancer, which reported that calcium and magnesium administration was effective for reducing the incidence and severity of oxaliplatin-induced neuropathy.[147] These results led to widespread routine use of calcium and magnesium infusions for neuroprotection. A subsequent prospective trial was halted early at an interim analysis, because it was determined that patients who were treated with calcium and magnesium infusions responded less well to chemotherapy. It was later determined that this conclusion was erroneous, as an independent radiologist reviewed computed tomography CT scan data from the trial and determined that there was no negative effect on chemotherapy response in calcium- and magnesium-treated patients.[30,148] A more recent double-blind study confirmed the lack of efficacy of calcium and magnesium infusions for prevention of oxaliplatin-induced neuropathy in patients with colon cancer.[149]

Table 13-7 Experimental Pharmacological Approaches to Prevent Drug-Induced Peripheral Neuropathy

Drug	Clinical Condition	Proposed Mechanism
Acetyl-L-carnitine[157,171-173]	CIPN and antiretroviral-induced PN	• Antioxidant effects, and stimulates mitochondrial DNA synthesis • Facilitates expression of nerve-growth factor
Amifostine[30,173-175]	CIPN	• Free radical scavenger
Calcium and magnesium salts[30,148,173-175]	CIPN	• Combats chelation of calcium and magnesium, thus preventing neuronal voltage-gated sodium channelopathy
Carbamazepine/oxcarbazepine[144,145,176]	CIPN	• Sodium-channel blockade to combat oxaliplatin-induced channelopathy
Erythropoeitin[114]	CIPN	• Erythropoietin receptor activation in neurons stimulates an antiapoptotic effect
Glutamine[105,114,141,142,177]	CIPN	• May upregulate or downregulate nerve growth factor, thus converting glutamine to the excitatory neurotransmitter glutamate
Vitamin E[173,174,177]	CIPN	• Reduction of oxidative stress induced by chemotherapy
Cannabinoids[178]	CIPN	• Activation of cannabinoid and/or 5-HT_{1A} receptors to modulate pain

5-HT = 5-hydroxytryptamine, CIPN = chemotherapy-induced peripheral neuropathy, DNA = deoxyribonucleic acid, PN = peripheral neuropathy.

A small placebo-controlled trial found that venlafaxine was effective for prevention of CIPN associated with oxaliplatin. Patients were randomized to venlafaxine or matching placebo to start 1 hour prior to the first oxaliplatin dose (50 mg of immediate-release venlafaxine). Treatment was continued with extended-released venlafaxine (37.5 mg twice daily) on days 2–11. Patients treated with venlafaxine experienced significantly lower rates of CIPN than those in the placebo group.[150]

MANAGEMENT

Unfortunately, pharmacologic measures to reliably treat drug-induced peripheral neuropathy have not been identified. The severity of symptoms of peripheral neuropathy can vary widely. Thus, although neuropathy may occur commonly in association with many drugs, it is often a predictable and tolerable occurrence, such that discontinuation of the causative drug is unnecessary. However, if symptoms are severe, initial treatment of drug-induced peripheral neuropathy should include discontinuation, or at least a reduction in the dose, of the offending agent. After discontinuation of therapy, pharmacologic measures to treat neuropathic pain should be used if symptoms are persistent. In cases such as cancer or HIV treatment, in which drug discontinuation is not possible, other approaches may be helpful. Strategies widely used for patients with peripheral neuropathy induced by antineoplastic regimens include reduction in dose intensity, extending drug-free intervals, and prolonging infusion times.[96,122,151] Another beneficial strategy is an alteration of the administration route. The most prominent example of this strategy involves the use of bortezomib for the treatment of multiple myeloma. In a pivotal phase III trial, subcutaneous administration was found to be as effective as intravenous administration, but was associated with a lower incidence of neuropathy.[152]

Discontinuation of therapy with antiretroviral agents may result in loss of HIV virologic control, and dose reduction is generally undesirable. Similarly, antituberculosis regimens including isoniazid and ethambutol can cause drug-induced peripheral neuropathy, but clinicians may resist modifying the dosage regimen because of concerns regarding the potential for the development of multidrug resistant tuberculosis (MDR-TB). Shin et al.[153] reviewed the management of peripheral neuropathy in patients undergoing treatment for MDR-TB. Antituberculosis medications were not discontinued in any of the 10 patients with presumed drug-induced peripheral neuropathy. The addition of amitriptyline therapy resulted in a favorable response in most patients. Therefore, medications to treat drug-induced peripheral neuropathy can be effective in reducing the frequency or severity of symptoms even if current neurotoxic medications are continued.

Unfortunately, although there are several medications that have shown promise in unblinded studies of drug-induced peripheral neuropathy or in anecdotal reports, evidence from randomized trials demonstrating efficacy is sparse. Duloxetine demonstrates efficacy for reducing pain in CIPN. In a randomized, double-blind study, taxane- or oxaliplatin-treated patients who received duloxetine experienced a greater reduction in pain than those receiving placebo.[154]

A triple agent topical gel containing baclofen, amitriptyline, and ketamine (BAK) has been used to treat peripheral neuropathic pain syndromes. This drug combination has the advantage of blending multiple mechanisms of action that could theoretically work synergistically. A placebo-controlled study of BAK in patients with CIPN reported a trend toward improvement of symptoms of neuropathic pain with minimal adverse effects.[155]

Acetyl-L-carnitine may be a promising agent for managing chemotherapy and antiretroviral toxic neuropathy. Two small unblinded studies in patients experiencing CIPN found acetyl-L-carnitine to be effective for reducing pain scores for up to 1 year, and therapy appeared to be well tolerated.[114,156] One placebo-controlled trial in patients with HIV and antiretroviral-induced neuropathy found a reduction in pain scores in patients treated acutely with intramuscular acetyl-L-carnitine compared to those treated with placebo, as well as improvements in symptoms during follow-up therapy with oral acetyl-L-carnitine.[157] Larger studies are necessary to confirm the results of these preliminary data.

Nerve growth factor (NGF)-1 therapy has been associated with encouraging results in patients with HIV-related neuropathy. Results of a double-blind study and the long-term (48-week) follow-up study showed a reduction in pain symptoms associated with subcutaneous NGF-1, although pain severity was not consistently reduced.[158-161] Unfortunately, the results of phase III studies with this agent in patients with diabetic neuropathy were negative, which limited further large-scale studies.[124] It must be reiterated that results from clinical studies regarding treatment of drug-induced peripheral neuropathy are often confounded by the fact that the disease state itself (HIV, cancer) often plays a role in causing neuropathy.

Other measures to treat pain or other neurologic manifestations are limited to symptomatic treatments used in other types of neuropathic pain, such as diabetic neuropathy or postherpetic neuralgia. Simple analgesics such as nonsteroidal anti-inflammatory drugs or acetaminophen often are associated with limited efficacy but are safe and inexpensive. Other drugs that are generally more effective for neuropathic pain tend to be either more costly or carry the burden of undesirable toxicities or drug interactions.

Tricyclic antidepressants have been used for several years and have been found to be effective in some clinical trials in patients with painful neuropathy. The results of two placebo-controlled trials, however, demonstrated only nonsignificant trends toward efficacy.[162,163]

Gabapentin has been shown to be effective in randomized clinical trials in patients with diabetic neuropathy and postherpetic neuralgia and is associated with few serious adverse effects or drug interactions.[164,165] Small studies have noted that gabapentin may be effective for the management of both HIV and cancer-related pain. An unblinded trial in 20 patients with cancer and neuropathy revealed that gabapentin not only reduced pain scores but also reduced the need for rescue pain medication.[166] In a small study in patients with HIV and sensory neuropathy, both pain and sleep scores improved in gabapentin-treated patients compared with those receiving placebo.[167] The incidence of gabapentin-induced somnolence was high in this particular cohort (80%), but otherwise this agent was generally well tolerated. In contrast, however, a phase III trial of gabapentin in 115 patients with CIPN proved disappointing. After 6 weeks of therapy with either gabapentin or matching placebo, the severity of pain scores was not improved in the treatment group.[168]

Lamotrigine, which has also been studied for the treatment of neuropathic pain syndromes, has demonstrated some benefit for the treatment of peripheral neuropathy in patients with HIV. In a double-blind, randomized trial, Simpson et al.[169] studied the effects of lamotrigine versus placebo in patients with HIV who were afflicted with peripheral neuropathy. Patients were stratified according to whether or not they were receiving neurotoxic antiretroviral agents. Pain scores were significantly improved in lamotrigine-treated patients who were currently receiving neurotoxic HIV medications. Other antiepileptic drugs, such as carbamazepine, topiramate, valproic acid, and pregabalin can be used if other treatments fail. Some of these antiepileptic medications, including topiramate and valproic acid, inhibit the metabolism of drugs that are substrates for the cytochrome P-450 system. Venlafaxine may also be effective for the treatment of drug-induced peripheral neuropathy. Topical preparations such as capsaicin and lidocaine are associated with a low incidence of systemic adverse effects and have been shown to be effective in treating neuropathic pain. Results with these agents, unfortunately, have been generally disappointing in patients with HIV-associated neuropathy, and thus their use should be restricted to adjunctive therapy if other options are ineffective.[158,170] Opioid analgesics and tramadol are also options in patients experiencing inadequate relief or intolerable neuropathy associated with other agents.

INFORMATION FOR PATIENTS

Patients for whom potentially neurotoxic drugs are prescribed should be instructed regarding the signs and symptoms of drug-induced peripheral neuropathy. Patients should understand that for many drugs, symptoms might not appear until late in therapy or even after therapy has been completed or discontinued. Patients should be instructed to consult their pharmacist or physician as soon as they begin to experience abnormal sensations or pain occurring in the extremities so that peripheral neuropathy can be identified sufficiently early to permit intervention. Finally, patients should make their pharmacist and physician aware of all medications they are taking to prevent the occurrence of drug interactions that may predispose them to drug-induced peripheral neuropathy.

CHAPTER 14

Visual Disturbances

Yaman Kaakeh and Steven R. Abel

Over 20 classes of drugs have been associated with the development of visual disturbances and ocular toxicities. The reported ocular effects range from benign and transient to very severe. Healthcare practitioners should be aware of these drug-induced visual disturbances in order to assess the cause of specific and sometimes serious ocular problems associated with medications.

CAUSATIVE AGENTS

Drugs and herbal supplements that have been reported to cause or exacerbate visual disturbances are listed in **Table 14-1**.[1-204] A wide array of medications can cause visual disturbances through various mechanisms. These ocular problems can occur despite administration at the recommended daily dose.

Many drug classes, such as antihistamines, antipsychotics, and tricyclic antidepressants possess anticholinergic properties that are known to induce visual disturbances. Some medications with strong anticholinergic effects may cause mydriasis, the basis of photophobia that may occur in patients using these agents. Often, these visual disturbances are associated with overdose (e.g., diphenhydramine) or topical or accidental introduction into the eye (e.g., scopolamine patch). Anticholinergics may also precipitate angle-closure glaucoma and aggravate open-angle glaucoma. Cycloplegia occurs to a lesser extent.[1-3,29]

Amiodarone, a widely used antiarrhythmic drug, is known to cause bilateral corneal deposits, especially when used for long durations at higher doses. Only minimal deposits develop in patients taking 100–200 mg daily. However, at doses exceeding 400 mg daily, corneal deposits develop in nearly 100% of patients. The majority of patients are unaffected by these deposits; only 4–9% of users report visual disturbances. Anterior subcapsular lens opacities and halo vision have been associated with amiodarone therapy, although to a lesser extent. One serious complication is optic neuropathy, which is relatively rare but can gradually progress to blindness. Because of its long half-life, amiodarone-induced optic neuropathy may progress even after discontinuation of therapy.[1,2,6,13,23-36]

The antimalarial agents chloroquine and hydroxychloroquine are known to cause ocular disturbances, although the former to a lesser extent.[1,2] Like amiodarone, these drugs can cause corneal deposits in nearly all patients, even at therapeutic doses. The majority of adverse ocular effects associated with these drugs are dose- and time-dependent. Maculopathy and retinopathy are rare and most commonly associated with long-term, high-dose therapy. Maculopathy is very serious, and is reversible only if diagnosed in its early phase. Macular changes may progress even after therapy is discontinued. Serious retinal toxicity associated with chloroquine can develop with cumulative doses exceeding 100 g. Retinopathy may develop after 1–3 years, but case reports have described onset in as little as 6 months. In contrast, the total daily dose, rather than the cumulative dose, appears to be more important with hydroxychloroquine. The risk of retinopathy is much lower when the daily dose is 6.5 mg/kg or less for up to 10 years. Blurred vision is rare and usually associated with high doses (500–700 mg/day). Cases of nyctalopia (night blindness) and oculogyric crisis have been reported in association with chloroquine.[2]

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances

Drug	Effect(s)	Incidence	Level of Evidence[a]
Acetazolamide[1-4,b]	Angle-closure glaucoma	NK	C
	Myopia	NK	B
Adalimumab[5]	Cataracts	<5%	A
Albuterol[1,4,c]	Mydriasis	NK	C
Alendronate[6-14]	Blurred vision	NK	B
	Conjunctivitis	NK	B
	Ocular pain	NK	B
	Scleritis	NK	B
	Uveitis	NK	B
Alfuzosin[6]	Amblyopia	NK	B
	Blurred vision	NK	B
	Floppy iris syndrome	NK	B
Allopurinol[1,15-19]	Cataracts	NK	B
Amantadine[1,4,20-22,d]	Corneal edema	0.1–1%[e]	A
	Corneal lesions	0.1–1%[e]	A
	Decreased vision	0.1–1%[e]	A
	Keratitis	NK	B
	Mydriasis	NK	B
	Oculogyric crises	NK	B
	Optic nerve palsy	0.1–1%	A
	Photosensitivity	0.1–1%	A
	Visual hallucinations	NK	B
Amiodarone[1,2,6,13,23-36,f]	Blurred vision	NK	B
	Corneal deposits	69–100%	A
	Halo vision	1.4–40%[e]	B
	Lens opacities	22–60%	A
	Optic neuropathy	1.3–1.8%	A
	Photophobia	NK	B
Amphetamine[1,2,4,g]	Decreased vision	NK	B
	Disturbed color vision	NK	B
	Mydriasis	NK	B
	Visual hallucinations	NK	B
Anidulafungin[37]	Blurred vision	<2%	A
	Ocular pain	<2%	A
Aripiprazole[38-40]	Chorioretinopathy	NK	C
	Myopia	NK	C
Anticholinergics[1-3,29,h]	Cycloplegia	NK	B
	Decreased accommodation	NK	B
	Decreased vision	NK	B
	Mydriasis	NK	B
	Photophobia	NK	B

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

Drug	Effect(s)	Incidence	Level of Evidence[a]
Aspirin[1,3,29,41]	Aggravation of sicca	NK	C
	Blurred vision	NK	C
	Intraocular hemorrhage	NK	C
	Myopia (transient)	NK	C
	Periorbital edema	NK	C
	Superficial punctate keratitis	NK	C
Atorvastatin[3,42-44]	Amblyopia	<2%	A
	Dry eyes	<2%	A
	Eye hemorrhage	<2%	A
	Glaucoma	<2%	A
	Ophthalmoplegia	NK	C
	Ptosis	NK	C
Barbiturates[1,2,i]	Disturbed horizontal ocular movement	NK	B
	Miosis	NK	B
	Mydriasis	NK	B
	Ptosis	NK	B
Benzonatate[45]	Blindness	NK	C
Bevacizumab[46]	Excessive lacrimation	>10%	A
Bishop's weed (*Ammi visnaga*)[47,48]	Phototoxicity	NK	C
Bitter orange (*Citrus aurantium*)[47,48]	Phototoxicity	NK	C
Black mustard (*Brassica nigra*)[47-49]	Eye irritation	NK	C
Botulinum toxin[50,51]	Bilateral inferior oblique palsies	NK	C
	Blindness	NK	C
	Diplopia	NK	C
Bromocriptine[35,52]	Blurred vision	NK	C
	Myopia	NK	C
Bupivacaine[53]	Cortical blindness	NK	C
Burning bush (*Dictamnus albus*)[47,48]	Phototoxicity	NK	C
Busulfan[1,32,54-56,j]	Cataracts	12–47%	B
Calcium-channel blockers[1,2,k]	Blurred vision	NK	B
	Transient blindness	NK	B
Canthaxanthine[6,13,47,48,57]	Crystalline retinopathy	NK	C
	Retinal deposits[e]	NK	C
Carbamazepine[1,35,41,58-60,l]	Blurred vision	Up to 5%[e]	B
	Conjunctivitis	NK	C
	Diplopia	Up to 17%[e]	B

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

Drug	Effect(s)	Incidence	Level of Evidence[a]
	Lens opacities	NK	C
	Oculogyric crises	NK	C
	Retinopathy	NK	C
Carmustine[1-3,35,41,61,62,m]	Arterial narrowing	NK	C
	Blurred vision	NK	C
	Conjunctivitis	NK	C
	Intraretinal hemorrhage	NK	C
	Neuroretinitis	NK	B
	Ocular pain	NK	C
	Retinal infarction	NK	C
Celecoxib[13,14,63-69]	Blurred vision	0.1–1.9%	A
	Chromatopsia	NK	C
	Conjunctivitis	0.1–1.9%	A
	Glaucoma	0.1–1.9%	A
	Ocular pain	0.1–1.9%	A
Celery (*Apium graveolens*)[47,48]	Phototoxicity	NK	C
Cetirizine[9,36,70,71]	Blindness	<2%	A
	Blurred vision	NK	C
	Keratoconjunctivitis sicca	NK	C
	Oculogyric crises	NK	C
	Pupillary changes	NK	C
	Xerophthalmia	<2%	A
Chamomile (*Matricaria chamomilla*)[6,13,47-49]	Allergic conjunctivitis	NK	C
Chaulmoogra (*Hydrocarpus*)[47,48]	Visual disturbances	NK	C
Chloramphenicol[1,3,29,n]	Optic neuritis	NK	B
	Retrobulbar neuritis	NK	B
Chlorella[47,48]	Photosensitivity	NK	C
Chloroquine[6,13,29,32,35,72-76,o]	Blurred vision	NK[e]	A
	Corneal deposits	Up to 95%[e]	A
	Maculopathy	<1%[e]	A
	Nyctalopia	NK	C
	Oculogyric crises	NK	C
	Retinopathy	<1%[e]	A
Chlorpheniramine[1-3,p]	Blurred vision	1%	B
	Decreased lacrimation	NK	B
	Mydriasis	NK	B
Chlorpromazine[1,3,29,32,35,77,q]	Cataracts/lens deposits	NK	B
	Conjunctival pigmentation	Up to 46%	B
	Corneal deposits	Up to 95%	B
	Epithelial keratopathy	NK	C

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

Drug	Effect(s)	Incidence	Level of Evidence[a]
	Eyelid pigmentation	NK	B
	Pupillary changes	NK	B
	Retinal pigment deposits	NK	C
Cimetidine[1,2,4]	Decreased vision	NK	B
	Mydriasis	NK	B
	Photophobia	NK	B
	Visual hallucinations	NK	B
Ciprofloxacin[78]	Blurred vision	<1%	A
	Decreased vision	<1%	A
	Diplopia	<1%	A
	Disturbed color vision	<1%	A
	Ocular pain	<1%	A
Clomiphene[1-3,79,r]	Blurred vision	1.5–10%[e]	A
	Mydriasis	5–10%[e]	B
	Optic neuropathy	NK	B
	Visual field changes	5–10%[e]	B
	Visual sensations	5–10%[e]	B
Clonidine[1,2,s]	Dry, itchy eyes	NK	B
	Miosis	NK	B
Contrayerva (*Dorstenia contrayerva*)[47,48]	Phototoxicity	NK	C
Corticosteroids[1,2,26,29,32,35,56,80,t]	Cataracts	10–40%[e]	A
	Decreased vision	NK	B
	Exophthalmos	NK	C
	Increased IOP	30%[e]	A
	Mydriasis	NK	B
	Myopia	NK	B
	Optic neuropathy	NK	C
	Papilledema	NK	B
	Pseudotumor cerebri	NK	B
Crizotinib[81]	Blindness	NK	C
	Optic neuropathy	NK	C
Cyclophosphamide[1,2,41,56,u]	Blepharoconjunctivitis	NK	B
	Blurred vision	Up to 17%	B
	Keratoconjunctivitis sicca	Up to 50%	B
	Optic neuropathy	NK	C
	Pinpoint pupils	NK	B
Cyclosporine[3,35,82,83]	Conjunctivitis	<2%	A
	Cortical blindness	NK	B
	Optic disk edema	2.5%	A
Cypress spurge (*Euphorbia cyparissias*)[47-49]	Conjunctivitis	NK	C
	Corneal defects	NK	C
	Eyelid swelling	NK	C

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

Drug	Effect(s)	Incidence	Level of Evidence[a]
Cytarabine[3,48,84,85,v]	Blurred vision	NK	B
	Corneal toxicity	Up to 80%	A
	Keratoconjunctivitis	Up to 100%	A
	Ocular burning	NK	B
	Photophobia	NK	B
Dapsone[86]	Vision loss	NK	C
Datura (*D. stramonium*, *D. wrightii*)[6,13,47,48]	Mydriasis	NK	C
Deferoxamine[87-89]	Blurred vision	<2%	B
	Maculopathy	NK	C
	RPE changes	<2%	B
Dextroamphetamine[1,2,4,g]	Decreased vision	NK	B
	Mydriasis	NK	B
	Visual hallucinations	NK	B
Diazepam[1,4,31,59,90]	Blurred vision	NK	B
	Conjunctivitis	NK	B
	Diplopia	NK	B
	Nystagmus	NK	B
Diazoxide[1,2,w]	Epiphora	Up to 20%	B
Diclofenac[29,63,91]	Abnormal vision	Up to 2%	B
	Corneal infiltrates	NK	C
	Photosensitivity	NK	C
Digitalis[1-3,29,35,92,x]	Blurred vision	16–20%[e]	B
	Decreased visual acuity	16–20%[e]	B
	Disturbed color vision	16–20%[e]	B
	Halo vision	16–20%[e]	B
	Retrobulbar neuritis	NK	C
Dimethyl sulfoxide[47,48]	Ocular burning	NK	C
Docetaxel[3,4,32,93,94]	Conjunctivitis	1.1–5.1%	A
	Epiphora	Up to 10%	A
	Open-angle glaucoma	NK	C
Doxazosin[6,95]	Amblyopia	NK	B
	Blurred vision	<1%	B
	Floppy iris syndrome	<1%	B
Doxorubicin[1,2,56,y]	Blurred vision	NK	B
	Conjunctivitis	NK	B
	Epiphora	Up to 25%	B
Duloxetine[96]	Blurred vision	3%	A
Echineacea purpurea[6,13,47,48]	Conjunctivitis	NK	C
Erlotinib[97-99]	Trichomegaly	NK	C
Ethambutol[1,2,5,12,25,28,31,34,100,z]	Retrobulbar neuritis	1–50%[e]	B

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

Drug	Effect(s)	Incidence	Level of Evidence[a]
Ethanol[1,3]	Decreased accommodation	NK	B
	Diplopia	NK	B
	Disturbed color vision	NK	B
	Mydriasis	NK	B
	Nystagmus	NK	B
Etidronate[6-9,13,14]	Blurred vision	NK	B
	Conjunctivitis	NK	B
Etodolac[61,101]	Blurred vision	1–3%	A
	Conjunctivitis	NK	C
Fingolimod[102-105]	Macular edema	0.5–1.5%	A
Fluorouracil[1,2,35,56,aa]	Cicatricial ectropion	NK	C
	Conjunctivitis	NK	C
	Corneal erosions	NK	C
	Epiphora	NK	C
	Optic nerve atrophy	NK	C
	Periorbital edema	NK	C
	Photophobia	NK	C
Fluoxetine[1,3,4,106,107,bb]	Abnormal vision	2%	A
	Conjunctivitis	0.1–1%	A
	Dry eyes	0.1–1%	A
	Eye tics	NK	C
	Mydriasis	0.1–1%	A
	Photophobia	0.1–1%	A
Fluvoxamine[4]	Amblyopia	3%	A
	Mydriasis	NK	C
Furosemide[1]	Blurred vision	NK	B
	Xanthopsia	NK	B
Gabapentin[1,108]	Amblyopia	2.7–4.2%	A
	Diplopia	1.2–5.9%	A
	Nystagmus	1–8.3%	A
	Visual hallucinations	0.1–1%	A
Gemcitabine[109]	Retinopathy	NK	C
Gentamicin[1,2,cc]	Pseudotumor cerebri	NK	B
Ginkgo biloba[6,13,47,48]	Spontaneous hyphema	NK	C
	Retinal hemorrhage	NK	C
	Retrobulbar hemorrhage	NK	C
Goa powder (*Andira araroba*)[47-49]	Conjunctivitis	NK	C
Gold[1,3,29,35,dd]	Corneal/conjunctival deposits	Up to 80%	A
	Lenticular deposits	36–55%	A
	Ophthalmoplegia	NK	C

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

Drug	Effect(s)	Incidence	Level of Evidence[a]
Guanethidine[1,2,ee]	Blurred vision	Up to 17%	A
	Conjunctivitis	NK	B
	Miosis	NK	B
	Ptosis	NK	B
Haronga (*Haronga madagascariensis*)[47,48]	Phototoxicity	NK	C
Henbane (*Hyoscyamus niger*)[47,48]	Impaired accommodation	NK	C
	Mydriasis	NK	C
Heparin[35]	Subconjunctival hemorrhage	NK	C
Herb paris (*Paris quadrifolia*)[47,48]	Miosis	NK	C
Hogweed (*Heracleum sphondylium*)[47,48]	Phototoxicity	NK	C
Horse chestnut (*Aesculus hippocastanum*)[47,48]	Visual disturbances	NK	C
Huperzine A[47,48]	Blurred vision	NK	C
Hyaluronic acid[110-112]	Diplopia	NK	C
Hydrochlorothiazide[1,4,29,41,b]	Angle-closure glaucoma	NK	B
	Decreased lacrimation	NK	B
	Myopia	NK	B
	Photosensitivity	NK	C
5-hydroxytryptophan[47,48]	Blurred vision	NK	C
	Mydriasis	NK	C
Hydroxychloroquine[1-3,6,13,29,32,35,36,72-74,113,ff]	Blurred vision	NK	B
	Corneal deposits	Up to 100%[e]	A
	Diplopia	NK	C
	Maculopathy	<1%[e]	A
	Retinopathy	<1%[e]	A
	Visual-field defects	NK	B
Hyoscine patches[114]	Photophobia	Up to 60%	B
Ibandronate[14,48,115]	Conjunctivitis	NK	B
	Scleritis	NK	C
	Uveitis	NK	C
Ibuprofen[3,29,35,63,116-120,gg]	Amblyopia	<1%	C
	Blurred vision	<1%	C
	Decreased vision	<1%	C
	Diplopia	NK	C
	Disturbed color vision	<1%	C
	Scotomata	<1%	C
	Uveitis	NK	C
	Visual field defects	<1%	C
	Vortex keratopathy	NK	C

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

Drug	Effect(s)	Incidence	Level of Evidence[a]
Imatinib[36,49,121-124]	Blurred vision	1–10%	A
	Conjunctivitis	1–10%	A
	Dry eyes	0.1–1%	A
	Epiphora	7–18%	A
	Glaucoma	<0.1%	A
	Macular edema	<0.1%	A
	Periorbital edema	Up to 74%	A
	Vitreous hemorrhage	<0.1%	A
Indomethacin[3,29,35,63,hh]	Blurred vision	NK	C
	Corneal deposits	NK	C
	RPE changes	NK	C
	Retinopathy	NK	C
	Retinopathy of prematurity	NK	C
Interferon[1,3,26,56]	Conjunctivitis	NK	B
	Decreased vision	NK	B
	Disk edema	NK	C
	Retinopathy	Up to 57%	B
Interleukin-2[1,2,125,ii]	Diplopia	NK	C
	Palinopsia	NK	C
	Visual field defects	NK	C
Isoniazid[1,13,jj]	Optic neuritis	NK	B
Isotretinoin[3,9,13,14,29,36,48,126-132]	Blepharoconjunctivitis	20–43%	B
	Blurred vision	16–27%	B
	Cataracts	NK	C
	Corneal deposits	5–7%	B
	Decreased vision	5.9%	B
	Dry eyes	14–33%	B
	Impaired dark adaptation	8%	B
	Intracranial hypertension	10%	B
	Myopia	NK	C
	Optic neuritis	1.9%	C
	Photophobia	5%	B
	Subconjunctival hemorrhage	1.4%	C
	Superficial punctate keratitis	Up to 22%	B
Kava kava (*Piper methysticum*)[47,48]	Impaired accommodation	NK	C
Ketorolac[133]	Abnormal vision	<1%	A
	Blurred vision	<1%	A
Lamotrigine[1,14,59,134,135]	Blurred vision	11–25%	A
	Conjunctivitis	NK	B
	Diplopia	24–49%	A
	Nystagmus	<5%	B

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

Drug	Effect(s)	Incidence	Level of Evidence[a]
Licorice[6,13,47,48]	Decreased vision	NK	C
	Visual disturbances	NK	C
Lily of the valley (*Convallaria majalis*)[47,48]	Disturbed color perception	NK	C
Linezolid[32,136,137,kk]	Blindness	NK	C
	Optic neuropathy	NK	C
Lithium[1-3,41]	Blurred vision	NK	B
	Decreased accommodation	Up to 10%	B
	Exophthalmos	11%	B
	Nystagmus	NK	B
	Ocular teratogenesis	NK	B
	Oculogyric crises	NK	C
	Papilledema	NK	C
	Photophobia	NK	C
Lorazepam[1]	Blurred vision	NK	B
	Conjunctivitis	NK	B
	Diplopia	NK	B
	Nystagmus	NK	B
Lovage (*Levisticum officinale*)[47,48]	Phototoxicity	NK	C
Lovastatin[3,34,138,139]	Blurred vision	1%	A
Mandrake (*Mandragora officinarum*)[47,48]	Mydriasis	NK	C
Marijuana[3,6]	Blurred vision	NK	C
	Dry eyes	NK	C
	Mydriasis	NK	C
	Photophobia	NK	C
	Nystagmus (with overdose)	NK	C
Masterwort (*Peucedanum ostruthium*)[47,48]	Phototoxicity	NK	C
Mechlorethamine[2,3,56]	Necrotizing uveitis	25%	B
Metformin[140]	Vision loss	NK	C
Methamphetamine[1,2,4,g]	Decreased vision	NK	B
	Mydriasis	NK	B
	Visual hallucinations	NK	B
Methanol[141-146]	Blindness	NK	B
	Blurred vision	NK	B
	Optic neuropathy	NK	B
	Optic nerve atrophy	NK	C
Methotrexate[1,3,29,56]	Blurred vision	NK	B
	Conjunctivitis	10–19%	B
	Periorbital edema	20–49%	B
	Optic neuropathy	NK	B

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

Drug	Effect(s)	Incidence	Level of Evidence[a]
Metronidazole[35,41]	Myopia	NK	C
	Oculogyric crises	NK	C
	Optic neuritis	NK	C
	Photophobia	NK	C
	Visual field defects	NK	C
Midazolam[1,3]	Blurred vision	<1%	B
	Conjunctivitis	NK	B
	Decreased accommodation	<1%	B
	Diplopia	<1%	B
	Miosis	<1%	B
	Nystagmus	<1%	B
Mountain laurel (*Kalmia latifolia*)[47,48]	Temporary loss of vision	NK	C
Nalidixic acid[1,2,ll]	Papilledema	NK	B
	Vision loss	NK	B
	Visual sensations	NK	B
Naproxen[1,3]	Cataracts	NK	C
	Corneal opacities	<1%	B
	Decreased vision	<5%	B
	Optic disk edema	<1%	B
	Optic neuritis	<1%	B
	Optic papillitis	<1%	B
Narcotics[1,2,mm]	Decreased accommodation	NK	B
	Diplopia	NK	B
	Epiphora	NK	B
	Irregular pupils	NK	B
	Miosis	NK	B
Niacin[6,13,47,48,147]	Blurred vision	25%	B
	Dryness	20%	B
	Eyelid edema	10%	B
	Cystoid macular edema	NK	B
Ocriplasmin[148-155]	Vision loss	NK	B
	Retinal dysfunction	NK	B
Oral contraceptives[1,3,26,35,nn]	Disturbed color vision	NK	B
	Optic neuritis	NK	B
	Pseudotumor cerebri	NK	B
	Retrobulbar neuritis	NK	B
Paclitaxel[1,3,4,32]	Decreased vision	20%[e]	B
	Open-angle glaucoma	NK	C
	Scintillating scotoma	43%[e]	B
	Vision loss	NK	C
Pamidronate[3,6-9,13,14,156,157]	Blurred vision	NK	B
	Conjunctivitis	<1%	B

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

Drug	Effect(s)	Incidence	Level of Evidence[a]
	Episcleritis	<1%	B
	Nerve palsy	NK	C
	Ocular pain	NK	B
	Photophobia	NK	B
	Ptosis	NK	C
	Retrobulbar neuritis	NK	C
	Scleritis	<1%	B
	Uveitis (anterior)	NK	B
	Xanthopsia	NK	C
Paroxetine[3,4,158]	Anisocoria	<0.1%	A
	Blurred vision	2–5%	A
	Conjunctivitis	0.1–1%	A
	Mydriasis	0.1–1%	A
	Optic neuritis	NK	B
Parsnip (*Pastinaca sativa*)[47,48]	Photosensitivity	NK	C
Phenmetrazine[1,2,4,oo]	Cataracts	NK	C
	Decreased vision	NK	B
	Mydriasis	NK	B
	Retinal venous thrombosis	NK	B
	Visual hallucinations	NK	B
Phenylbutazone[1,2,pp]	Conjunctivitis	NK	B
	Decreased vision	NK	B
	Optic neuritis	NK	C
	Retinal hemorrhage	NK	B
Phenytoin[29,35]	Cataracts	NK[e]	B
	Diplopia	NK	B
	Disturbed color vision	NK	B
	Nystagmus	NK	B
	Ophthalmoplegia	NK	C
Pimpinella (*Pimpinella major*)[47,48]	Photosensitivity	NK	C
Pregabalin[159]	Abnormal vision	Up to 5%[e]	A
	Blurred vision	1–12%[e]	A
	Diplopia	Up to 12%[e]	A
Propofol[3,35,160,qq]	External ophthalmoplegia	NK	C
	Conjunctival chemosis	NK	C
Propolis[47,48]	Conjunctivitis	NK	C
Psyllium (*Plantago ovata, P. afra*)[47-49]	Allergic conjunctivitis	NK	C
Pyrethrum (*Chrysanthemum cinerarifolium*)[47,49]	Irritative conjunctivitis	NK	C
	Keratitis	NK	C
Quetiapine[6,rr]	Cataracts	<0.1%	C

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

Drug	Effect(s)	Incidence	Level of Evidence[a]
Ranitidine[1,2,4]	Diminished vision	NK	B
	Disturbed color vision	NK	C
	Mydriasis	NK	B
	Photophobia	NK	B
	Visual hallucinations	NK	B
Reserpine[1,2,ss]	Conjunctivitis	NK	B
	Miosis	NK	B
Risedronate[6-9,13,14]	Blurred vision	NK	B
	Conjunctivitis	NK	B
	Ocular pain	NK	B
	Scleritis	NK	B
	Uveitis	NK	B
Risperidone[161]	Abnormal vision	1–7%	A
	Conjunctivitis	<1%	A
Rosiglitazone[162]	Macular edema	NK	C
Rue (*Ruta graveolens*)[47,48]	Photosensitivity	NK	C
Scopolia[47,48]	Impaired accommodation	NK	C
Sertraline[163]	Diplopia	NK	C
Sildenafil[3,6,13,32,36,164-170,tt]	Blurred vision	3–50%[e]	A
	Disturbed color vision	3–50%[e]	A
	Increased brightness	3–50%[e]	A
	NAION	NK	B
	Other ocular effects in clinical trials[uu]	<2%	A
	Ocular effects in postmarketing phase[vv]	NK	B
Solifenacin[171]	Blurred vision	3.8–4.8%[e]	A
	Dry eyes	0.3–1.6%[e]	A
Spironolactone[1]	Decreased vision	NK	B
	Myopia	NK	B
St. John's wort (*Hypericum perforatum*)[47,48]	Photosensitivity	NK	C
Streptokinase[172]	Blindness	NK	C
Strophanthus (*Strophanthus kombe*)[47,48]	Disturbed color perception	NK	C
Sulfamethoxazole–trimethoprim[2,4,41,173]	Angle-closure glaucoma	NK	B
	Myopia	NK	B
	Uveitis	NK	B
Sulfonamides[1,4,14,35,41,173-175,ww]	Decreased vision	NK	B
	Myopia	NK	B
	Optic neuritis	NK	B
	Photosensitivity	NK	B
	Uveitis	NK	C

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

Drug	Effect(s)	Incidence	Level of Evidence[a]
Tacrolimus[176]	Maculopathy	NK	C
Tadalafil[3,6,13,169,177,178,e]	Blurred vision	<2%	A
	Conjunctivitis	<2%	A
	Disturbed color vision	<0.1%	A
	Eyelid edema	<2%	A
	Increased lacrimation	<2%	A
	NAION	NK	B
	Ocular pain	<2%	A
	Retinal artery occlusion	NK	B
	Retinal vein thrombosis	NK	B
	Visual field defect	NK	B
Tamoxifen[1,3,6,13,29,32,35,179-181,xx]	Cataracts	8%	A
	Corneal opacities	1–11%	B
	Disturbed color vision	NK	B
	Optic neuritis	<2%	B
	Retinopathy	1–6.3%	B

	Scleritis	NK	B
	Uveitis	NK	B
Zonisamide[204]	Angle-closure glaucoma	NK	C

IOP = intraocular pressure, NAION = nonarteritic anterior ischemic optic neuropathy, NK = not known, RPE = retinal pigment epithelium.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Acute myopia may last 24–48 hours. Probably caused by an increase in anteroposterior diameter of the lens, which may be reversible even if drug use is continued.

[c] Only 30 reported cases of mydriasis; 1 case of bilateral narrow-angle glaucoma precipitated by use of albuterol.

[d] Diffuse, white punctate subepithelial corneal opacities have been reported, occasionally associated with superficial punctate keratitis. Onset has been 1–2 weeks after initiation of therapy with doses of 200–400 mg/day. Resolves with drug discontinuation.

[e] Dose-dependent ocular effect.

[f] Corneal deposits are dose- and duration-related; resembles chloroquine keratopathy. Deposits are bilateral, reversible, and unassociated with visual symptoms. Patients taking 100–200 mg/day have only minimal deposits. Deposits occur in ~100% patients receiving 400 mg/day. In addition, anterior subcapsular lens opacities have been reported. Rarely, such opacities may progress, increasing in density and in the diffuse distribution of the deposits. Because of amiodarone's photosensitizing properties, it is thought that light exposure may result in lens changes.

[g] Ocular effects reported with high doses; can induce or exacerbate narrow-angle glaucoma.

[h] Systemic and transdermal anticholinergic agents may cause mydriasis and, less frequently, cycloplegia. Mydriasis may precipitate angle-closure glaucoma. Photophobia is related to the mydriasis. Accommodation is decreased for near objects.

[i] Most significant ocular adverse effects occur in long-term users or in toxic states. Pupillary responses are variable; miosis occurs most frequently, except in toxicity, when mydriasis predominates. Nystagmus and weakness in extraocular muscles may be seen. Chronic abusers exhibit a characteristic ptosis.

[j] Reported with high doses.

[k] Primarily blurred vision; transient blindness at peak concentrations has been observed in several patients.

[l] Ocular adverse effects when dose >1–2 g/day; disappears when dose decreased.

[m] These ocular effects are not well established. Evidence of delayed bilateral ocular toxicity in 2 of 50 patients treated with high-dose intravenous carmustine (800 mg/m^2). Symptoms of ocular toxicity became evident 4 weeks after intravenous treatment. Evidence of delayed ocular toxicity (mean onset, 6 weeks) ipsilateral to the site of infusion developed in 7 of 10 patients treated with intraarterial carotid doses of carmustine to a cumulative minimum of 450 mg/m^2 in two treatments.

[n] Optic neuritis occurs more frequently than retrobulbar neuritis. Rare unless a total dose of 100 g and duration >6 weeks are exceeded. Vision usually improves after drug discontinuation.

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

[o] Patients using ordinary doses may have white-yellow corneal deposits in as little as 3 weeks; little effect on visual function. Serious retinopathy when total dose >100g; usually develops after 1–3 years, but can occur in 6 months. Visual loss may progress from peripheral to central and be associated with changes in color vision. Blurred vision is rare and usually associated with high doses (500–700 mg/day). Macular changes may progress even after the drug is discontinued.

[p] Blurred vision occurs rarely (~1% of patients taking 12–14 mg/day). Decreased lacrimation may lead to contact lens intolerance or aggravate keratoconjunctivitis sicca. Mydriasis is rare, but may precipitate angle-closure glaucoma.

[q] Deposits rare when total dose <500 g. Visible after a total dose of 1 kg in most cases; incidence may increase to 90% after ≥2.5 kg. Usually, deposits do not affect vision. The cornea and conjunctiva may be affected after the lens shows pigment changes. Minimal retinal pigment deposits; further documentation is necessary.

[r] Ocular adverse effects occur in 5–10% of patients. Blurred vision is the most common effect, although visual sensations such as flashing lights, distortion of images, and various colored lights (primarily silver) may occur.

[s] Dry eyes are rare; reversible upon discontinuation of therapy. Miosis may occur in overdose.

[t] Posterior subcapsular cataracts have been associated with systemic administration. Risk is increased in patients who have received >15 mg/day of prednisone or its equivalent for >1 year. Bilateral posterior subcapsular cataracts associated with nasal or inhalation of beclomethasone dipropionate have been reported rarely. Most patients have received therapy for >5 years, often at higher-than-recommended doses. About 40% of patients also were receiving systemic corticosteroids. An elevation in IOP is more common with topical corticosteroids than with systemic therapy, but this is of little consequence in patients without pre-existing glaucoma. Patients with glaucoma should be monitored routinely if receiving systemic corticosteroids. Papilledema is primarily associated with long-term therapy, and the incidence appears to be greater in children than in adults. Intracranial hypertension or pseudotumor cerebri associated with systemic corticosteroids has been well-documented.

[u] Blurred vision is common; onset within 24 hours of receiving high-dose intravenous cyclophosphamide; resolves within 1 hour to 2 weeks. Conjunctivitis is a well-established adverse effect of therapy. Miosis occurs secondary to parasympathomimetic effects. In addition, cyclophosphamide has been reported to potentiate cataract formation when used in combination with corticosteroids. However, more information is needed before a causal relationship can be confirmed.

[v] Corneal toxicity and conjunctivitis have been reported with high-dose (3 g/m^2) therapy.

[w] Increased lacrimation may continue after drug is discontinued.

[x] A glare phenomenon and a snowy appearance in objects have been associated primarily with digitalis intoxication. In a small number of cases, reversible reduction in visual acuity has been noted. Also associated with changes in the visual fields.

[y] Effects may last for several days after discontinuation of treatment.

[z] At doses of 15 mg/kg/day, virtually devoid of ocular adverse effects. Such effects are rare at doses of 25 mg/kg/day for a duration of a few months. Patients treated for prolonged periods should undergo routine visual examinations including visual fields. Most effects are reversible after therapy is discontinued.

[aa] Ocular effects are reversible and seldom interfere with continued therapy.

[bb] Administration of 20–40 mg/day has been associated with paroxysmal contractions of the muscles around the lateral aspect of the eye. This effect occurred 3–4 weeks after initiation of fluoxetine therapy and resolved within 2 weeks following discontinuation.

[cc] Rare, but has been well documented with secondary papilledema and visual loss.

[dd] Deposition in the conjunctiva and superficial cornea more common than in the lens or deep cornea. Incidence in cornea of 40–80% in total doses of ≥1.5 g. Lens deposits observed in 36–55% of patients on long-term therapy (>3 years; lowest cumulative dose, 2.5 g). Visual acuity is unaffected and deposits resolve 3–12 months after discontinuation of therapy.

[ee] Sporadically documented. One study reported a 17% incidence of blurred vision in patients taking 70 mg/day.

[ff] See chloroquine comments (n). Incidence of corneal deposits up to 100% after 4 or more years of therapy. At <4 years incidence is ~1–28%, much lower than that associated with chloroquine.

[gg] Rare; blurred vision has been reported in patients taking from four 200-mg tablets/week to six tablets/day. Changes in color vision have rarely been reported.

[hh] Rare; changes in color vision have rarely been reported.

[ii] Visual complications have occurred during the first or second treatment cycle, usually within 5–6 days after initiation of therapy. Ocular symptoms included diplopia, binocular negative scotomata (isolated areas of varying size and shape in which vision is absent or depressed. These are not perceived ordinarily but may be apparent upon completion of a visual-field examination), and palinopsia (abnormal recurring visual imagery). In most cases, treatment was continued for the entire planned duration of therapy. Symptoms resolved after discontinuation of therapy.

[jj] Prevalence not well defined, but appears to be significantly less common than peripheral neuritis. Evaluation is difficult because most patients are malnourished, chronic alcoholics, or receiving multiple medications. Pre-existing eye disease does not appear to be a predisposing factor.

[kk] Only 12 reported cases of optic neuropathy associated with extended use (>28 days). Duration of therapy ranged from 5–11 months before development of optic neuropathy.

[ll] Visual sensations are most common. Main feature: a brightly colored appearance of objects, occurring soon after the drug is taken. Although quinolone antibiotics are nalidixic acid derivatives, they have rarely been associated with these ocular side effects. Visual loss appears to be temporary; lasting between 30 minutes and 72 hours. Papilledema can also occur, secondary to increased intracranial pressure, primarily in infants and young children. This is reversible upon discontinuation.

[mm] Miosis often with morphine in normal doses; slight with other agents. The effect is secondary to central nervous system action on the pupilloconstrictor center. Other effects are associated with narcotic withdrawal.

[nn] Optic neuritis is quite rare. In patients with retinal vascular abnormalities, use of oral contraceptives may not be prudent. Numerous other possible ocular adverse effects are associated with these agents, and further documentation is required.

[oo] Ocular effects reported with high doses; can induce or exacerbate narrow-angle glaucoma. There have only been a few case reports linking phenmetrazine with cataracts; further documentation is needed.

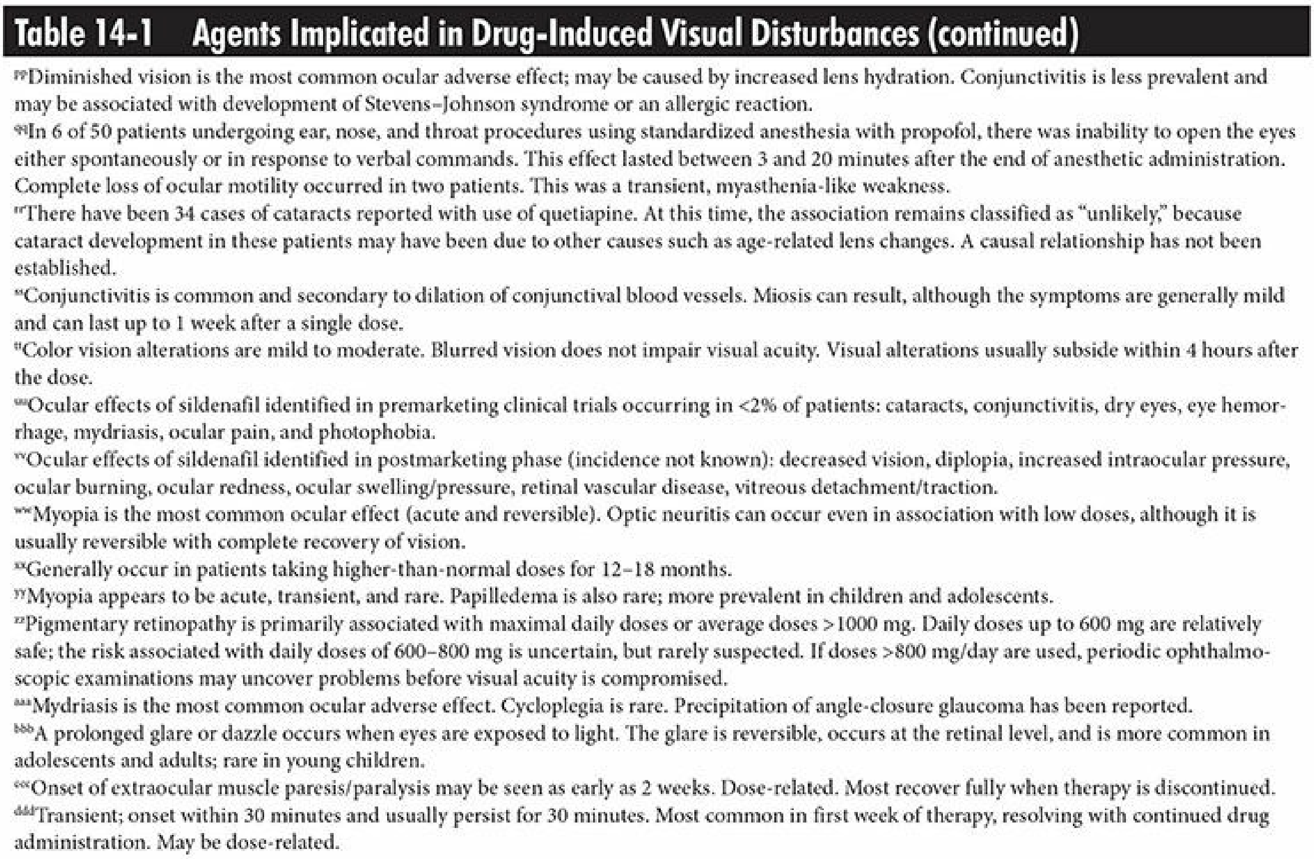

Table 14-1 Agents Implicated in Drug-Induced Visual Disturbances (continued)

[pp] Diminished vision is the most common ocular adverse effect; may be caused by increased lens hydration. Conjunctivitis is less prevalent and may be associated with development of Stevens–Johnson syndrome or an allergic reaction.

[qq] In 6 of 50 patients undergoing ear, nose, and throat procedures using standardized anesthesia with propofol, there was inability to open the eyes either spontaneously or in response to verbal commands. This effect lasted between 3 and 20 minutes after the end of anesthetic administration. Complete loss of ocular motility occurred in two patients. This was a transient, myasthenia-like weakness.

[rr] There have been 34 cases of cataracts reported with use of quetiapine. At this time, the association remains classified as "unlikely," because cataract development in these patients may have been due to other causes such as age-related lens changes. A causal relationship has not been established.

[ss] Conjunctivitis is common and secondary to dilation of conjunctival blood vessels. Miosis can result, although the symptoms are generally mild and can last up to 1 week after a single dose.

[tt] Color vision alterations are mild to moderate. Blurred vision does not impair visual acuity. Visual alterations usually subside within 4 hours after the dose.

[uu] Ocular effects of sildenafil identified in premarketing clinical trials occurring in <2% of patients: cataracts, conjunctivitis, dry eyes, eye hemorrhage, mydriasis, ocular pain, and photophobia.

[vv] Ocular effects of sildenafil identified in postmarketing phase (incidence not known): decreased vision, diplopia, increased intraocular pressure, ocular burning, ocular redness, ocular swelling/pressure, retinal vascular disease, vitreous detachment/traction.

[ww] Myopia is the most common ocular effect (acute and reversible). Optic neuritis can occur even in association with low doses, although it is usually reversible with complete recovery of vision.

[xx] Generally occur in patients taking higher-than-normal doses for 12–18 months.

[yy] Myopia appears to be acute, transient, and rare. Papilledema is also rare; more prevalent in children and adolescents.

[zz] Pigmentary retinopathy is primarily associated with maximal daily doses or average doses >1000 mg. Daily doses up to 600 mg are relatively safe; the risk associated with daily doses of 600–800 mg is uncertain, but rarely suspected. If doses >800 mg/day are used, periodic ophthalmoscopic examinations may uncover problems before visual acuity is compromised.

[aaa] Mydriasis is the most common ocular adverse effect. Cycloplegia is rare. Precipitation of angle-closure glaucoma has been reported.

[bbb] A prolonged glare or dazzle occurs when eyes are exposed to light. The glare is reversible, occurs at the retinal level, and is more common in adolescents and adults; rare in young children.

[ccc] Onset of extraocular muscle paresis/paralysis may be seen as early as 2 weeks. Dose-related. Most recover fully when therapy is discontinued.

[ddd] Transient; onset within 30 minutes and usually persist for 30 minutes. Most common in first week of therapy, resolving with continued drug administration. May be dose-related.

Ocular adverse effects associated with the antiepileptic medications are not uncommon. Blurred vision, diplopia, and nystagmus are well-documented adverse effects of carbamazepine and phenytoin.[135] Downbeat nystagmus has been described as a consequence of lamotrigine therapy in two patients. In both cases, plasma lamotrigine concentrations were supratherapeutic, and the nystagmus was reversible upon correction of plasma concentrations.[134] There have also been numerous case reports linking topiramate with acute secondary bilateral angle-closure glaucoma.[190]

The bisphosphonate drugs have been linked to a number of ocular inflammatory adverse effects, including nonspecific conjunctivitis and anterior uveitis. They are currently the only drugs reported to cause scleritis.[7,8,156] Although this is a rare occurrence, scleritis is a serious condition associated with ocular pain and may lead to vision loss.[7] Selective phosphodiesterase-5 inhibitors, such as sildenafil, tadalafil, and vardenafil are commonly associated with transient visual disturbances, namely changes in color perception, blurred vision, and photophobia. These effects are largely dose-dependent. Sildenafil appears to carry the greatest dose-dependency, with impaired color perception observed at the standard 50-mg dose (3%), and increasing in incidence to 11% and 40–50% in association with the 100-mg and 200-mg doses, respectively. There are also reports of nonarteritic anterior ischemic optic neuropathy (NAION) in patients using selective phosphodiesterase-5 inhibitors. However, a causal relationship cannot yet be confirmed, as other risk factors may have been involved.[6,164,166,168]

Other drug classes associated with ocular adverse effects include analgesics, anticoagulants, antidepressants, anti-infectives, antihyperlipidemics, antineoplastic agents, barbiturates, benzodiazepines, β-adrenergic blockers, calcium-channel blockers, corticosteroids, hypouricemics, immune modulators, and oral contraceptives.[1,2] Numerous visual disturbances have also been reported in association with the use of herbal and nutritional supplements.[3,6,13,47-49,57]

EPIDEMIOLOGY

The exact incidence of drug-induced visual disturbances is not known. Numerous factors including the specific medication, frequency of administration, cumulative dose, genetic factors, and route of administration may influence the occurrence of drug-induced visual disturbances. For example, 5% of patients undergoing therapy with topical corticosteroids experience an increase in intraocular pressure of 16 mm Hg or greater, while 30% experiences an increase of 6–15 mm Hg following 4 weeks or more of treatment.[205,206] Further assessment documented that primary open-angle glaucoma developed in 13% of high corticosteroid responders (defined as >15 mm Hg increase) and ocular hypertension occurred in 63.8%. Open-angle glaucoma developed in no low responders (<5 mm Hg increase) and ocular hypertension occurred in only 2.4%.[207]

Corneal opacities occur in 70–100% of patients receiving amiodarone, while optic neuropathy develops in approximately 2%. The anticonvulsant lamotrigine causes diplopia and blurred vision with incidences of 22% and 15%, respectively.[1] Agents used for erectile dysfunction (sildenafil, vardenafil, tadalafil) are associated with dose-dependent changes in color vision, blurred vision, increased light perception, and visualization of flashing lights in 3–50% of patients.[1] High-dose cytarabine has been associated with blurred vision and keratitis in 100% of treated patients. Decreased visual acuity, diplopia, and color vision defects have been reported with nonsteroidal anti-inflammatory drugs (NSAIDs) even in patients taking small doses infrequently.[1] The known incidences of visual disturbances associated with specific drugs are provided in Table 14-1.

MECHANISMS

The pathogenesis of drug-induced visual disturbances appears to be multifactorial. Cumulative or daily dose, duration of therapy, properties of specific medications, and site of drug action all appear to play a role. Although we are knowledgeable about mechanisms of visual disturbances associated with some drugs, mechanisms have yet to be described for the majority of medications. Known mechanisms can be divided into direct and indirect drug effects on the ocular structures (**Table 14-2**).

The blood–aqueous barrier and posterior blood–retinal barrier serve to naturally defend the intraocular structures of the eye from exogenous compounds or toxins. However, some compounds may penetrate the tight junctional areas between retinal pigment epithelium (RPE) cells and within the retinal capillary endothelium. Over time, this can lead to a number of ocular problems, such as epithelial keratopathy or pigmentary deposition. Medications may also interact directly with RPE cells, resulting in retinotoxicity. For example, the antimalarial drugs chloroquine and hydroxychloroquine exhibit high affinity for melanin in RPE and may induce photoreceptor degradation, leading to the development of a “bulls-eye” maculopathy.[34,208]

Amphiphilic compounds, such as amiodarone, accumulate in lysosomes and cannot be eliminated effectively. This leads to the accumulation of the drug in intracytoplasmic lamellar bodies in the eye. The resulting complex with cellular phospholipids on the epithelium cannot be metabolized by lysosomal phospholipids, and corneal deposits occur. These deposits are dose- and duration-related and resemble chloroquine-induced keratopathy.[33,34,208] Amiodarone also causes optic neuropathy, although the mechanism is less clear. It is thought that a vascular occlusion from a decrease in axoplasmic flow may be involved. This may result in optic disk edema that progresses to optic neuropathy.[31,33] Amiodarone-induced optic neuropathy is sometimes difficult to distinguish from NAION because patients may already have underlying vascular disease.[6]

Table 14-2 Mechanisms of Drug-Induced Visual Disturbances

Effect	Mechanisms
Angle-closure glaucoma	Associated with mydriasis, which causes closure of the anterior chamber angle, preventing elimination of aqueous humor from the eye; may also result from swelling of the lens or other ocular tissues
Blepharoconjunctivitis	Drug concentrating in the tears causing irritation and subsequent inflammation of the eyelids and conjunctiva
Blurred vision	Direct ocular effects (see: Dry eyes, keratoconjunctivitis sicca, mydriasis) or indirect effects in nonocular areas (central nervous system depression, cranial-nerve damage, hypertension, etc.)
Cataracts/lens opacities	Medications may precipitate as fine granules, typically in the superficial cortex of the lens and in the anterior capsule
Color vision disturbances	Impairment of retinal-cell function through direct effect of medications on the ocular tissues; may occur at therapeutic plasma drug concentrations
Conjunctival pigmentation	Direct deposition of medication in cysts within conjunctival epithelium
Corneal deposits	Accumulation of the drug in the intracytoplasmic lamellar bodies in the eye; these bodies form complexes with cellular phospholipids that cannot be

	metabolized by lysosomal phospholipids, and corneal deposits result; may be time- or concentration-dependent, or both
Diplopia	See: Dry eyes, keratoconjunctivitis sicca, mydriasis
Dry eyes	Secretion of medication by lacrimal gland, leading to local eye irritation; medications may also indirectly lead to inadequate tear production and subsequent irritation
Epiphora	Excessive lacrimation due to local irritation of the eye or obstruction of tear ducts, thus preventing the drainage of tears
Exophthalmos	Unknown
Extraocular muscle paresis	Cranial-nerve palsy, which may lead to dysfunction in one or more extraocular muscles
Floppy iris syndrome	α1-adrenergic blocking effect (alfuzosin, terazosin, etc.) may also selectively block receptors in the iris dilator muscle, leading to atrophy of the iris dilator smooth muscle
Halo vision	Unknown
Intraocular pressure increases	See: Angle-closure glaucoma
Keratoconjunctivitis sicca	Secretion of medication by lacrimal gland, leading to local eye irritation; medications may also lead indirectly to inadequate tear production and subsequent irritation
Mydriasis	Sympathetic stimulation may cause contraction of the radial muscle, and subsequent dilation of the iris; mydriasis may precipitate or exacerbate angle-closure glaucoma
Necrotizing uveitis	Medications may cause uveitis through direct toxicity or indirect mechanisms, including stimulation of the immune system to develop antidrug antibodies; drug combining with melanin and inducing uveitis by reducing the pigment’s free radical scavenger properties; antibiotics stimulating the immune system by liberating antigens from dead microorganisms
Nonarteritic anterior ischemic optic neuropathy (NAION)	Caused by reduced blood flow to the optic nerve; the most common ocular adverse effect found in nearly all patients treated with long-term amiodarone is reversible keratopathy, known as vortex keratopathy; this neuropathy is typically bilateral and symmetric; NAION, nonarteric ischemic optic neuropathy, rarely occurs simultaneously in both eyes; its symptoms often resolve in weeks; the onset is more insidious, and the degree of visual loss is less
Nystagmus	Cerebellovestibular dysfunction; dose-related, potentially irreversible cerebellar deficits
Optic neuropathy	Decrease in axoplasmic flow may lead to vascular occlusion, resulting in optic disk edema that progresses to optic neuropathy; compromised axonal transport in optic nerve that leads to optic neuropathy; may be time or concentration-dependent, or both
Periorbital edema	Allergic reaction; with imatinib, it is presumed that inhibition of platelet-derived growth factor in dermal dendrocytes of the periorbital skin may result in a decrease in interstitial fluid pressure, which may lead to localized edema
Ptosis	Cranial nerve palsy, which may lead to dysfunction in one or both upper eyelid elevator muscles
Retrobulbar neuritis	Drug chelates retinal-cell copper, which acts as a cofactor for mitochondrial functioning in the optic nerve; consequentially, axonal transport in the optic nerve may be compromised and progress to optic neuropathy

Superficial punctate keratitis	Unknown

The mechanism of ethambutol-induced optic neuropathy remains incompletely understood. It is postulated that ethambutol chelates retinal-cell copper, which acts as a cofactor for mitochondrial functioning in the optic nerve. As a result, axonal transport in the optic nerve may be compromised, leading to optic neuropathy. These effects appear to be dose- and time-dependent.[13]

An increase in intraocular pressure, caused by certain medications such as corticosteroids, can exacerbate open-angle glaucoma. Mydriatics and mydriatic/cycloplegics could exacerbate angle-closure glaucoma, because this is an anatomical event. Secretion of medications through the lacrimal gland can lead to blurred vision, eye and contact-lens discomfort, dry eye symptoms, and conjunctivitis.

Drug-induced ocular effects are time-dependent, suggesting that tissue accumulation likely plays a role in the pathophysiology.[33] Visual disturbances can also result from the indirect actions of certain medications on nonocular structures. Blurred vision is a common adverse effect of anticholinergic medications and benzodiazepines. Phenytoin may cause cerebellar degeneration and eventually lead to irreversible cerebellar deficits. Vision changes may be an indication of toxic plasma drug concentrations.[1] Drugs that lead to hypertension, metabolic abnormalities, sedation, or dehydration may also lead to visual problems. Nystagmus induced by carbamazepine and phenytoin may be due to cerebellovestibular dysfunction.[58]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms of drug-induced visual disturbances are listed in **Table 14-3**. The onset of signs and symptoms is largely time-dependent, meaning that they are more likely to occur later in therapy. In some cases, drug-induced visual disturbances may mimic the signs and symptoms of other diseases, requiring clinicians to carefully evaluate each contributing factor that might result in their patients' visual disturbances. Various methods of diagnosis are used to identify drug-induced eye disease. These are similar to diagnostic tests and methods used with eye disease that is not drug-induced. Principles such as onset of symptoms in relationship to the initiation of drug therapy are key. The time frame for certain adverse ocular effects of drugs is known, and should stimulate certain diagnostic tests. One example is the increase in intraocular pressure that may be associated with the administration of topical corticosteroids. The maximum intraocular pressure increase occurs within 4 weeks, so it makes sense that intraocular pressure should be measured once or twice during that time period. **Table 14-4** lists conditions that should be considered in the differential diagnosis of drug-induced visual disturbances.

Table 14-3 Signs and Symptoms Associated with Drug-Induced Visual Disturbances[209]

- Blepharitis
- Blindness
- Blurred vision
- Cataracts
- Color vision alterations
- Conjunctivitis
- Decreased vision (miosis, mydriasis)
- Diplopia
- Glaucoma
- Halos around lights
- Hallucinations
- Hazy vision
- Increased intraocular pressure
- Keratopathy
- Night blindness
- Optic neuropathy
- Photophobia
- Pseudotumor cerebri
- Scleritis
- Tunnel vision
- Vertigo
- Visual field constriction

Table 14-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Visual Disturbances[31,34,209]

- Stroke
- Concussion
- Dehydration
- Encephalopathy
- Exposure to environmental toxins
- Drug intoxication
- Glaucoma
- Head trauma
- Hypertension
- Intracranial lesions/infarction
- Macular degeneration
- Migraine
- Metabolic disorders (i.e., diabetes, Wilson disease)
- Neoplasm
- Psychiatric disease

- Retinal disease/detachment
- Seizures
- Vitreous detachment

Hypersensitivity reactions including dermatitis are most likely to affect the eyelids. Quinolones may cause hyperpigmentation of the eyelids, while 5-fluorouracil is associated with blepharitis and conjunctivitis involvement.[32] Keratoconjunctival disorders present mainly as conjunctival hyperemia (red eye) with or without superficial corneal involvement.[31] Medications that are structurally related to sulfonamides may induce swelling of the ciliary body leading to the development of angle-closure glaucoma.[32]

Agents that dilate the pupil (adrenergics, anti-cholinergics) may cause blurred vision or precipitate angle-closure glaucoma in patients with narrow anterior chamber angles. Angle-closure glaucoma is a medical emergency. Symptoms include swelling of the eye, clouding of the cornea, and severe pain. Corticosteroids can increase intraocular pressure (IOP) in genetically predisposed patients, resulting in ocular hypertension of open-angle glaucoma.[205,206] Although corticosteroid-induced increases in IOP are associated most frequently with topical ophthalmic preparations, systemic corticosteroids may cause a similar response, although with a lesser magnitude.[210]

Docetaxel and paclitaxel have also been associated with the development of open-angle glaucoma.[32] Unlike angle-closure glaucoma, ocular hypertension and open-angle glaucoma are silent diseases that are frequently symptom-free until there has been significant damage to the optic nerve, resulting in a reduction of the visual field. Patients may describe a loss of central or peripheral vision.

Corticosteroids, allopurinol, phenothiazines, and busulfan have been reported to cause cataracts.[31] Symptoms of cataracts include a reduction in visual clarity and a reduced ability to see in low light or darkness. Many drugs administered systemically reach the retina via the systemic circulation. Phenothiazines may bind to melanin, causing a severe phototoxic retinopathy.[32] Amiodarone appears to cause a bilateral optic neuropathy that is similar to NAION, a condition also associated with the use of cGMP (cyclic guanosine monophosphate)–specific phosphodiesterase-5 inhibitors for erectile dysfunction.[32] Amiodarone has also been associated with lens deposits and keratopathy due to corneal alterations related to a drug-induced lipid storage disorder.[211] Symptoms of keratopathy include glare and photophobia.

RISK FACTORS

In some instances, the risk of visual disturbances associated with medications is influenced by genetic factors. An example of this is the propensity for topical corticosteroids to cause increases in intraocular pressure. Myocilin is a protein, encoded by the *MYOC* gene, which is linked to the most common form of glaucoma (open angle). Overexpression of myocilin due to corticosteroid administration augments the pressure response.[212] Studies suggest that heterozygotes are at medium risk, while homozygotes are at higher risk.[213] Unfortunately, there is no reliable genomic test to assess individuals prior to treatment to determine the likelihood for exaggerated and potentially adverse response to these medications.

In other cases, the risk for visual disturbances is increased with the daily drug dose, the cumulative drug dose, or both, as well as the use of combinations of medications associated with the development of visual disturbances. Underlying disease states may predispose patients taking certain medications to visual disturbances. The risk of corticosteroid-induced ocular hypertension is greater in patients with high myopia, diabetes mellitus, or connective-tissue disease (particularly rheumatoid arthritis).[210] The best approach to minimize the risk of drug-induced visual disturbances involves accurate diagnosis, including all underlying disease states and pre-existing drug therapy (prescription and nonprescription drugs and natural remedies), past therapeutic response to medications, including adverse events, and careful patient monitoring based on the benefit-to-risk ratio of medications administered. Practitioners must also recognize that some ocular disorders will occur regardless of careful prescribing or monitoring practices. For example, while age-related cataracts are slowly progressive, the potential for their development exists in everyone, depending upon longevity. Ocular symptoms often occur at plasma concentrations within the therapeutic range. The effects may be more marked at higher plasma concentrations.[214] **Table 14-5** lists other risk factors associated with drug-induced visual disturbances.

Table 14-5 Risk Factors for Drug-Induced Visual Disturbances

- Anatomic predisposition (e.g., narrow anterior chamber angles)
- Concomitant use of multiple drugs, including herbal therapies, that may cause visual disturbances (see Table 14-1)
- Cumulative dose (e.g., chloroquine, >100 g)
- Daily dose (e.g., hydroxychloroquine 500–700 mg/day)
- Genetics (e.g., myocilin and topical ophthalmic corticosteroids)
- Underlying disease states/conditions (see Table 14-4)

MORBIDITY AND MORTALITY

In general, the ocular side effects of drugs should have minimal overall adverse impact on the healthcare system in terms of hospitalizations or length of stay, and pose a relatively small risk of mortality. Most adverse events are managed through consultation within the office setting. Certain adverse events such as acute angle-closure glaucoma could result in emergency department visits. Conceivably, drug-induced loss of vision could result in a situation associated with bodily harm or death (i.e., personal or motor vehicle accident).

Left untreated, acute emergencies such as drug-induced angle-closure glaucoma could result in the permanent loss of sight in one or both eyes. Any acute or chronic reduction in visual acuity, as well as clinically significant reactions such as conjunctivitis could be associated with diminished quality of life.

PREVENTION

Some topically administered ocular medications are associated with systemic toxicities that can include visual disturbances. Topical atropine has been associated with blood pressure changes that affect vision. The use of punctal occlusion minimizes systemic absorption of the topically administered medication and therefore reduces, but does not eliminate, the associated risk. Punctal occlusion involves the application of pressure to the inner canthus with the index finger following topical administration of ophthalmic medication. Ideally, pressure should be applied for approximately 2 minutes. However, use of this technique, even for shorter periods, reduces the potential for systemic absorption of the topically administered medication.

The development of visual disturbances associated with systemic medications is frequently related to the average daily dose administered, the duration of treatment, and the cumulative dose. Prescribers are encouraged to consider the potential for visual disturbances associated with prescribed medications and to appropriately monitor patients. Healthcare providers may consider avoiding certain drugs, such as phosphodiesterase-5 inhibitors, in patients already at high risk for certain ocular diseases, such as NAION. Although there are only case reports linking these agents to NAION, these patients may already have compromised optic nerves due to vascular disease. It is postulated that these medications can lead to further neural function damage.

In some situations, visual disturbances occur in association with medications that may be monitored via the assessment of plasma concentrations (e.g., phenytoin). In such cases, therapeutic drug monitoring is suggested as appropriate based on clinical management of the patient and the potential for or suspicion of visual disturbances associated with the medication.

Routine ophthalmic examinations should be completed in all individuals. The usual frequency for examinations in patients without risk is every 2 years for individuals 18–60 years of age, and yearly thereafter. Patients with risk factors, including medications that may be associated with visual disturbances, should be seen more frequently (at least annually). In addition, patients should be educated regarding the necessity for follow-up visits if they receive medications that might be associated with the development of visual disturbances. Prescribers should carefully consider any underlying conditions that might make a patient more susceptible to visual disturbances associated with medications. Product information is another valuable tool in enabling individuals to assess the potential for a medication to induce visual disturbances. Approaches to help prevent drug-induced visual disturbances are outlined in **Table 14-6**.

Table 14-6 Approaches to Help Prevent Drug-Induced Visual Disturbances

- Be aware of the potential for visual disturbances
- Discontinue therapy prior to reaching total cumulative dose associated with visual disturbances
- Use punctal occlusion for topical ophthalmic medications with the potential for systemic adverse effects
- Restrict daily dose to minimize risk of visual disturbances
- Routine ophthalmic examinations

MANAGEMENT

Relatively little information exists regarding the effective management of drug-induced visual disturbances and ocular toxicities. The decision to discontinue, change, or even continue therapy with the offending agent is dependent on multiple factors (risk versus benefit, availability of alternative agents, severity of disease). The key to appropriate management is early identification.

Nonprescription or prescription medications (decongestants, artificial tears, NSAIDs) may be used to manage mild visual disturbances such as blurred vision or conjunctivitis. Discontinuation of the offending agent is usually necessary to ameliorate drug-induced visual disturbances. This is especially true for more serious ocular problems, such as retinopathy or maculopathy. Discontinuation of bisphosphonates is necessary for resolution of scleritis. Visual effects associated with cyclooxygenase-2 inhibitors typically resolve within 72 hours of drug discontinuation. Ocular adverse effects induced by phenytoin often resolve with discontinuation of therapy or dose reduction, although in some cases nystagmus may persist for 20 months or longer.[1] Intraocular pressure elevation, such as that caused by corticosteroids, is an indication to taper therapy. Left uncontrolled, significant increases in intraocular pressure could result in blindness. The antimalarial medications chloroquine and hydroxychloroquine may produce retinopathy and maculopathy. These effects are usually irreversible unless identified in the very early stage. Progression may occur and management may be limited to interventional pharmacology or surgical intervention.

In situations in which discontinuation of therapy is not always feasible (i.e., amiodarone), reducing the dose may help attenuate some of the visual disturbances. This is especially true for obese patients, who may be receiving above-normal doses of certain medications, such as gentamicin.

INFORMATION FOR PATIENTS

Appropriate patient education is the key to preventing and reducing the impact of drug-induced visual disturbances. The use of punctal occlusion when administering topical ophthalmic medications reduces the potential incidence of systemic side effects. The risks and benefits of a particular therapy should be thoroughly conveyed to the patient. Routine ophthalmic examinations are central to eye health assessment, and patients should have follow-up examinations at the recommended frequency. Patients should be advised to disclose all prescription, nonprescription, and herbal medications to their healthcare provider. Any rapid or sudden changes in visual acuity should also be reported.

CHAPTER 15

Delirium

Matthew A. Fuller

Delirium is a common and sometimes fatal disorder characterized by disturbance of consciousness and change in cognition that develops over a short period of time.[1] Delirium may have numerous etiologies, including drugs.

CAUSATIVE AGENTS

Drug-induced delirium may be caused by a wide array of drugs; however, there are a few agents that are consistently associated with the development of the disorder.[2-6] These include high-risk drugs that possess anticholinergic properties, such as low potency antipsychotics, tricyclic antidepressants, older antihistamines, sedative hypnotics, corticosteroids, and narcotics (**Table 15-1**).[7-100]

Other drugs vary in their propensity to cause delirium. For instance, exposure to opioids has been shown to increase the risk of delirium in patients with cancer; however, effectively treating pain with opioids in postoperative patients may actually reduce the risk of developing delirium.[17,101,102] The incidence of postoperative delirium approaches 50%.

In a meta-analysis, the association between psychoactive medications and the development of delirium in hospitalized patients was assessed.[103] This meta-analysis reviewed 28 studies that included several classes of psychoactive medications such as antiparkinsons, anticonvulsants, anticholinergics, antiemetics, antidepressants, antipsychotics, benzodiazepines, corticosteroids, histamine-type H_2 antagonists, nonsteroidal anti-inflammatory drugs, and opioid analgesics. Only psychoactive medications (grouped together) were found to be associated with the development of delirium. No individual medication was significantly associated with delirium.

EPIDEMIOLOGY

Delirium is very common and has been reported in 14–24% of patients at hospital admission, up to 56% of hospitalized patients, as many as 60% of individuals in nursing homes, and up to 88% of those in palliative care.[104-106] Most patients have multiple etiologies rather than a single cause of delirium, especially if they are burdened with medical problems or are elderly.

Table 15-1 Agents Implicated in Drug-Induced Delirium

Drug	Incidence	Level of Evidence[a]
ANTIPSYCHOTICS		
Clozapine[7]	10.1%	B
Fluphenazine[13]	NK	C
Haloperidol[12]	NK	C
Loxapine[16]	NK	C
Olanzapine[11,96]	1.4%	B
Perphenazine[14]	NK	C
Quetiapine[9]	NK	C
Risperidone[10]	NK	C
Thioridazine[15]	NK	C
Ziprasidone[8]	NK	C
OPIOIDS[27]		
Fentanyl[18,19]	NK	B
Meperidine[19,95]	RR 2.4, 95% CI 1.3–4.4	B

CORTICOSTEROIDS		
Prednisone[20,21,27,97]	13%	C
ANTIARRHYTHMICS		
Amiodarone[25]	NK	C
Lidocaine[23]	NK	C
Quinidine[26]	NK	C
Tocainide[24]	NK	C
DIGOXIN[26,27]	NK	B
ALCOHOL WITHDRAWAL[22]	NK	B
ANTIASTHMATICS		
Theophylline	NK	C
ANTICONVULSANTS		
Phenytoin[28]	NK	C
Acetazolamide[29]	NK	C
Lamotrigine[30]	NK	C
Pregabalin[31]	NK	C
Tiagabine[32]	NK	C
Valproic acid[33,57]	4.1/100 person-years	B
ANTIDEPRESSANTS		
Tricyclics		
Protriptyline[34]	NK	C
Desipramine[35,36]	NK	B
Clomipramine[37]	NK	C
Amitriptyline[14,38]	NK	C
Imipramine[39]	NK	C
Doxepin[40]	NK	C
Selective Serotonin Reuptake Inhibitors		
Fluoxetine[34,41]	NK	C
Paroxetine[42]	NK	C
Sertraline[12]	NK	C
Miscellaneous		
Bupropion[43]	NK	C
Venlafaxine[44]	NK	C

Monoamine Oxidase Inhibitors		
Phenelzine47	NK	C
Tranylcypromine46	NK	C
DOPAMINERGIC AGENTS		
Amantadine48	NK	C
Levodopa49	NK	C
Bromocriptine50	NK	C
BENZODIAZEPINES[95]	OR 3, 95% CI 1.3–6.8	B
Lorazepam51	NK	C
Diazepam52	NK	C
Clonazepam53	NK	C
Alprazolam54	NK	C
Triazolam55	NK	C
Clorazepate56	NK	C
LITHIUM[16,57]	2.8/100 person-years	B
NSAIDs		
Diclofenac58	NK	C
Ibuprofen59	NK	C
Ketoprofen60	NK	C
Sulindac61	NK	C
Indomethacin62	NK	C
Salicylic acid63	NK	C
COX-II INHIBITORS		
Celecoxib64	NK	C
ACE INHIBITORS65		
Enalapril	NK	C
Captopril	NK	C
MISCELLANEOUS ANTIHYPERTENSIVES65		
Reserpine	NK	C
Clonidine	NK	C
Methyldopa	NK	C
CALCIUM CHANNEL BLOCKERS		
Nifedipine67	NK	C

Verapamil[66]	NK	C
BETA BLOCKERS		
Atenolol[69]	NK	C
Metoprolol[70]	NK	C
Propranolol[13,68]	NK	C
ANTIMICROBIALS		
Aminoglycosides		
Tobramycin[71]	NK	C
Macrolides		
Azithromycin[72]	NK	C
Clarithromycin[73]	NK	C
Cephalosporins		
Cephalexin[74]	NK	C
Cephalothin[75]	NK	C
Cefazolin[76]	NK	C
Penicillins		
Piperacillin–tazobactam[77]	NK	C
Fluoroquinolones[98]		
Ciprofloxacin[78]	NK	C
Gatifloxacin[79]	NK	C
Ofloxacin[80]	NK	C
Levofloxacin[81]	NK	C
Miscellaneous		
Chloramphenicol[82]	NK	C
Trimethoprim–sulfamethoxazole[83]	NK	C
Linezolid[84]	NK	C
Ertapenem[99]	3.3–5.1%	C
HISTAMINE-H$_2$ ANTAGONISTS		
Cimetidine[85]	NK	C
Ranitidine[86]	NK	C
Nizatidine[87]	NK	C
Famotidine[88]	NK	C
ANTICHOLINERGICS[89,100]		

Atropine[90]	NK	C
Benztropine[12,13,91]	NK	C
Diphenhydramine[84,94]	OR 2.3, 95% CI 1.4–3.6	B
Scopolamine[92]	NK	C
Tolterodine[93]	NK	C

ACE = angiotensin-converting enzyme, CI = confidence interval, COX = cyclo-oxygenase, NK = not known, NSAID = nonsteroidal anti-inflammatory drug, OR = odds ratio, RR = relative risk.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Although the majority of cases are believed to be multifactorial, medications, particularly when patients are taking multiple drugs (polypharmacy), have been cited as the single cause of delirium in 12–39% of cases.[4] Aside from drug causes, other frequently identified etiologies of delirium include sensory and environmental issues (poor vision and hearing), infection, and fluid and electrolyte disturbances.[107]

MECHANISMS

There is a paucity of data describing mechanisms of drug-induced delirium. Some mechanisms have been determined through electrophysiological and biochemical studies and brain scans (**Table 15-2**).[108] The presence of anatomical lesions may lead to development of delirium; symptoms are related to the location of the lesion.

Table 15-2 Mechanisms of Drug-Induced Delirium

Drug(s)	Mechanism
Amitriptyline Atropine Benztropine Clomipramine Clozapine Desipramine Doxepin Imipramine Olanzapine Protriptyline Quetiapine Scopolamine Thioridazine Tolterodine	Decreased acetylcholine function

Amantadine Levodopa Bromocriptine	Excess dopamine function
Prednisone	Excess glucocorticoid activity
Alprazolam Clonazepam Clorazepate Diazepam Lorazepam Triazolam	Decreased GABA concentration
Fluoxetine Paroxetine Sertraline	Serotonin dysfunction

GABA = gamma-aminobutyric acid.

Acetylcholine has been implicated as the major neurotransmitter involved in the development of delirium. Despite various locations of lesions or other neurochemical changes, acetylcholine appears to be the final common pathway involved.[109] This is consistent with the acetylcholine hypothesis of cognitive impairment in neurocognitive disorders such as those due to Alzheimer disease. Elderly patients develop an age-related decrease in acetylcholine reserve, making them more vulnerable to acute changes in plasma acetylcholine concentrations. Further support for this theory is the relationship between the administration of anticholinergic drugs and cognitive deficits, particularly a reduction in the ability to focus or maintain attention and short-term memory deficits. Tune and Egeli[109] studied 88 patients meeting criteria for delirium (n = 47) or dementia (n = 41) and found that those with delirium were taking a significantly larger number of anticholinergic medications than those with dementia. It is unlikely that acetylcholine is the sole neurotransmitter involved in the development of delirium, given its interaction with dopamine transmission.[110] Dopamine exerts an inhibitory effect on the release of acetylcholine.

Glucocorticoid excess also has been implicated in the development of delirium.[111] Preclinical and clinical data support the hypothesis that increases in plasma glucocorticoid concentrations associated with various disorders, including depression, dementia, and Cushing syndrome, lead to cognitive impairment. Even modest increases in plasma glucocorticoid concentrations over a period of 5–6 years have led to reduced hippocampus-dependent memory and hippocampus volumes. There also may be a diminishment in the hypothalamic-pituitary-adrenal axis negative feedback loop in response to elevated plasma glucocorticoid concentrations as well as an increased sensitivity to adrenocorticotrophic hormone stimulation.

Other possible neurotransmitters involved in the pathogenesis of delirium include gamma-aminobutyric acid (GABA), glutamate, β-endorphins, and serotonin.[112] Cerebrospinal fluid sampling in elderly patients with delirium revealed diminished somatostatin-like and β-endorphin-like immunoreactivity. Therefore, although acetylcholine most commonly has been implicated in the development of delirium, the complete pathogenesis remains unknown but is likely multifactorial. A detailed review of the neuropathogenesis of delirium has been published.[113]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), characterizes delirium as a disturbance in attention, awareness, and cognition that develops over a brief period of time.[1] Symptoms of drug-induced delirium do not differ from those associated with delirium from other causes (**Table 15-3**).[1,2,5] There may be a prodromal syndrome of anxiety, changes in sleep patterns, disorientation, irritability, and restlessness 1–3 days prior to the full onset of delirium. Following the prodromal syndrome, patients develop disturbances of consciousness, cognition, psychomotor function, and, in some cases, sleep patterns. These disturbances develop over a short period of time (hours to days), and the symptoms fluctuate throughout the course of the day, making recognition of the disorder difficult.[5,104] Patients may be easily distracted and have a decreased awareness of their environment. Cognitive deficits such as disorientation to place and time, dysarthria, and loss of recent memory are common. Some patients develop perceptual disturbances such as delusions, illusions, or hallucinations. Psychomotor activity may present as hyperactive, hypoactive, or mixed types. Hyperactivity is characterized by agitation, restlessness, and emotional lability. Hypoactivity is characterized by withdrawal, flat affect, lethargy, and diminished responsiveness. Hypoactivity occurs more frequently than hyperactivity, and is unrecognized in as many as 66–84% of hospitalized patients.[114] In a study of patients in an intensive care unit (ICU), 1.6%, 43.5%, and 54.1% of patients were diagnosed with hyperactive, hypoactive, and mixed delirium, respectively.[114] Patients with mixed psychomotor symptoms fluctuate between hypoactive and hyperactive symptoms throughout the day. The sleep-wake cycle is often disrupted, and patients may experience insomnia, daytime drowsiness, or a complete reversal of the sleep cycle. Emotional disturbances such as anxiety, depression, fear, anger, irritability, aggression, or euphoria occur commonly.

Table 15-3 Signs and Symptoms Associated with Drug-Induced Delirium

- Autonomic activation (dilated pupils, dry mouth, flushing, sweating, tachycardia)
- Coma
- Decreased ability to sustain or focus attention
- Disorientation to time or place
- Dysarthria
- Dysgraphia
- Dysnomia
- Easily distracted
- Electroencephalogram abnormalities (generalized theta or delta slow-wave activity)
- Emotional disturbances (anger, anxiety, fear, euphoria, apathy, depression)
- Emotional lability
- Hallucinations
- Hyperactivity (picking at things, trying to get out of bed)
- Illusions
- Memory deficit (recent memory)
- Misinterpretations/misperceptions
- Neurologic abnormalities (unsteady gait and tremor)
- Rambling, pressured, or incoherent speech
- Restlessness
- Sleep disturbances
- Sluggishness or lethargy
- Stupor

The incidence of delirium is very high in certain populations, including older postoperative patients (15–53%), those in an ICU (70–87%) or nursing home (60%), and patients at the end of life (up to 83%).[104] Geriatric, oncologic, pediatric, and psychiatric patients are also at significant risk for developing delirium.[103,108]

Any evaluation of a patient for drug-induced delirium must include a careful and thorough medication history. One must assess patients' use of herbal products, complementary medicines, nonprescription medications, and drugs of abuse, as they have been implicated in provoking delirium. Furthermore, a social history that includes alcohol or illicit drug use should alert the clinician to the potential for delirium, which may occur in association with drug or alcohol withdrawal.[2,115] In the majority of cases, a multitude of etiologies exists, including drugs, and all possibilities must be considered.

The diagnosis of drug-induced delirium is purely clinical, as there are no laboratory tests that can definitively diagnose the disorder. Along with the medical history and clinical observation, the use of rating scales may assist in confirming the diagnosis. In just a few minutes, clinicians can complete a simple screening tool for delirium, the confusion assessment method (CAM), which has been adapted to other settings, such as the ICU (CAM-ICU).[116,117] The mini-mental state examination (MMSE) may also be used to screen patients for delirium. Other scales, such as the delirium rating scale (DRS) and the memorial delirium assessment scale (MDAS), are used to monitor symptoms over time.[118,119]

Differentiating delirium from other disorders may be difficult as symptoms may overlap considerably. Delirium is frequently underdiagnosed. Studies report that delirium occurring in patients on general medical units is not diagnosed in 32–67% of cases.[120] It may also be difficult to distinguish drug-induced delirium from that occurring as a result of other etiologies. Conditions to consider in the differential diagnosis of drug-induced delirium are listed in **Table 15-4**.

Table 15-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Delirium

- Dehydration
- Delirium not caused by drugs
- Dementia
- Depression
- Drug/alcohol use or withdrawal
- Fever
- Heart failure
- Hepatic insufficiency
- Hypercalcemia
- Hypo-, hypernatremia
- Hypoglycemia
- Hypoxia
- Infection
- Intoxication
- Kidney disease
- Mania
- Metabolic disturbances
- Shock
- Uremia

Patients with drug-induced delirium usually develop symptoms during intoxication, over an extended period of time with continuous drug use, or during drug or alcohol withdrawal. Delirium during acute intoxication presents within minutes to hours after ingestion of the substance (e.g., cocaine, hallucinogens).[121] The potential for delirium is increased if additional agents with anticholinergic activity also are ingested. A drug-induced delirium also may develop secondary to the accumulation of a drug or its metabolite over an extended period of time (e.g., barbiturates, alcohol) or as a result of a combination of a suspect medication and a pre-existing medical condition.[1,122] Withdrawal delirium may last a few hours to several weeks, depending on the half-life of the causative agent. This type of delirium results from lower tissue and body fluid concentrations than those to which the body has become accustomed. Withdrawal delirium may also be precipitated by a drug interaction, lowering the dose of a medication, or increased drug clearance such as that which may occur during dialysis or due to changes in kidney or liver function.[123]

Although most underlying causes of delirium often can be easily ruled out, dementia is often confused with delirium.[1,5,122] Memory impairment is common to both delirium and dementia; however, delirium is associated with impairment in consciousness during which patients are not alert or oriented to time or place. In addition, symptoms that develop rapidly and fluctuate throughout the day are more consistent with delirium than dementia. Differentiation between the two disorders is important and may require a more complete history from family or caregivers (**Table 15-5**).[124]

RISK FACTORS

Specific risk factors for delirium have been identified (**Table 15-6**). It is unknown if the risk factors for drug-induced delirium are different from those for delirium secondary to other causes.

Table 15-5 Clinical Features That Distinguish Delirium and Dementia[124]

Clinical Feature	Delirium	Dementia
Onset	Sudden	Insidious
Course	Fluctuating	Stable
Attention	Disordered	Normal
Cognition	Disordered	Impaired
Consciousness	Reduced	Clear
Delusions	Fleeting	Usually absent
Hallucinations	Usually visual	Usually absent
Involuntary movements	Asterixis or course tremor	Usually absent
Orientation	Usually impaired	Often impaired
Physical illness or drug toxicity	Present	Often present
Psychomotor activity	Altered	Normal
Speech	Often incoherent	Word finding difficulty and perseveration

Table 15-6 Risk Factors for Drug-Induced Delirium

- Acid–base imbalance
- Advanced age
- Anemia
- Cardiac arrhythmias

- Concomitant alcohol use
- Concomitant use of multiple drugs that may cause delirium
- Heart failure
- Dementia
- Depression
- Fever
- Fluid/electrolyte abnormality
- Head trauma
- Hepatic insufficiency
- Hypoalbuminemia
- Hypoglycemia
- Hypoxia
- Impaired physical function
- Infection
- Kidney disease
- Myocardial infarction
- Neoplasm
- Pain
- Parkinson disease
- Poor nutrition
- Respiratory failure
- Seizure disorder
- Sensory deprivation
- Severe illness
- Shock
- Sleep deprivation

A decrease in the metabolism or elimination of psychoactive drugs is a risk factor for drug-induced delirium. In some patients, diminished metabolism may be linked to drug interactions, heart failure, hepatic insufficiency, and/or kidney disease. The anticholinergic effects of psychoactive compounds may contribute to delirium via increased neuronal excitability and rate of neuronal adenosine triphosphate consumption, release of dopamine and glutamate, and stimulation of the sympathetic nervous system. Postoperative pain is also a risk factor for delirium (moderate pain: OR 2.2, 95% CI 1.2–4; severe pain: OR 3.7, 95% CI 1.5–9).[102]

A number of medical conditions are recognized as potential risk factors for the development of delirium and may also increase the risk of drug-induced delirium. Diagnoses of dementia or cognitive impairment have been identified as risk factors for delirium.[5,125] Disorders that affect neuronal functioning may cause delirium, including cerebral infarction, seizures, head trauma, vascular disease, Parkinson disease, and dementia.[2,5,125] Various metabolic abnormalities may contribute to the development of delirium, including electrolyte disturbances, kidney disease, hepatic insufficiency, edema from heart failure, thiamine deficiency, and acid-base imbalance.[2,121] Conditions that lead to changes in the delivery of oxygen or nutrients to the central nervous system also may predispose patients to delirium, such as myocardial infarction, cardiac arrhythmias, heart failure, respiratory failure, chronic obstructive pulmonary disease, anemia, hypoxia, or shock. Recently, alcohol abuse, hypertension, and higher APACHE (Acute Physiology and Chronic Health Evaluation) II scores have been identified as risk factors for delirium.[126]

Infection and fever also increase the risk of delirium. Hyperthermia causes a central release of norepinephrine, glutamate, and dopamine, which may predispose the patient to delirium.[121] Patients with human immune deficiency virus (HIV) infection may develop delirium caused by viral infection of neuronal tissue, opportunistic infection of the central nervous system, or metabolic encephalopathy.[127,128] Antibiotics, antivirals, or antifungal agents may be involved in drug interactions contributing to delirium.

Cancer increases the risk of delirium possibly due to associated liver or kidney disease, prerenal azotemia, hyperosmolality, dehydration, medications (e.g., opioids), hypoxia, disseminated intravascular coagulation, recent surgery, metastasis to the brain or other areas of the central nervous system, and infection.[129,130] In addition, patients undergoing treatment for cancer are often undergoing therapy with complex medication regimens associated with drug interactions that increase the potential for delirium.

The increased risk of delirium in postoperative patients appears to be linked to common occurrences such as infection, hypoxia, myocardial ischemia, metabolic derangement, decreased mobility, and exposure to anticholinergic drugs.[123,131] The increased risk in this population does not correlate with the number of previous surgeries, the duration of the surgical procedure, the type of anesthesia used, or the surgical technique employed.

Conditions of deprivation, including both sleep and sensory deprivation (hearing loss, visual impairment, and immobility), such as that which occurs in an ICU, have been found to be risk factors for delirium.[132] An interventional study of patients with deprivation-associated delirium found that nonpharmacologic interventions such as providing a relaxing night-time environment, hearing aids, glasses or magnifying glasses, large print materials, other forms of communication, and exercise may lower the incidence of delirium.[133] Benzodiazepine use may also be a risk factor for the development of delirium in adult ICU patients.[117]

Advanced age is considered to be a risk factor for delirium, because elderly patients are more likely to have multiple predisposing risk factors.[1,3,110,121-123,132,134] Physiologic changes in the elderly may alter drug transport across the blood-brain barrier making them more vulnerable to central nervous system effects. The presence of at least one copy of the apolipoprotein e4 allele on chromosome 19 increased the risk of postoperative delirium in elderly patients (OR 3.64, 95% CI 1.51–8.77).[133] The National Institute for Health and Care Excellence (NICE) reported that the greatest risk for delirium was associated with chronic cognitive decline or dementia (OR 6.30, 95% CI 2.89–3.74) and aortic aneurysm surgery (OR 8.3, 95% CI 3.6–19.4).[135] In addition, there may be age-related changes in metabolism or elimination that lead to drug accumulation in the elderly.[115] As patients age, the number of concomitant medical conditions and medications generally increases. These factors, along with the potential for increased sensitivity to some psychoactive medications, may contribute to the increased incidence of drug-induced delirium in this age group.

MORBIDITY AND MORTALITY

Few data are available regarding morbidity and mortality specifically associated with drug-induced delirium. However, delirium in general is associated with higher rates of long-term care placement and increased mortality rates.[132] Medical complications such as immobility, skin breakdown, falls, and aspiration pneumonia occur more commonly in patients with delirium.[5,136] These additional medical problems lead to prolonged duration of hospitalization, an increased rate of functional decline necessitating institutionalization, and increased mortality.[5,132,137-142] Drug-induced delirium is an unfortunate event that leads to increased healthcare costs that are almost completely avoidable.[132]

In the months to years after a delirium episode, patients are at risk for delayed recovery and poor functional status.[114,143] Of 126 patients who were diagnosed with delirium in one study, 64% reported the same number of delirium symptoms 1 week later, and 12% had a larger number of symptoms.[143] Patients with persistent delirium had lower activities of daily living scores than those who did not develop delirium. Another study of 77 elderly patients on medical, surgical, and geriatric hospital units indicated that frailty (OR 2, 95% CI 1.2–3.5) and poor recognition of delirium (OR 18.2, 95% CI 2.2–153.2) were associated with an increased risk of poor outcome including functional decline or death.[144]

Other serious outcomes of delirium include persistent or worsening cognitive function and an increased risk of developing dementia.[114] Rockwood and colleagues examined the risk of dementia and death over a 3-year period in previously hospitalized patients over the age of 65 years.[138] After adjusting for age, sex, and comorbid illnesses, there was an increased risk of dementia after an episode of delirium (OR 5.97, 95% CI 1.83–19.54). Delirium was also associated with an increased risk of death (OR 1.71, 95% CI 1.02–1.87). Kelly and colleagues reported that 18% of elderly nursing home residents who were hospitalized for acute medical illness and developed delirium died during their inpatient stay.[142] Of those who were discharged, an additional 18.4% died within 1 month, and another

13.3% died within 3 months. The cumulative mortality in this study was 46.6% at 3 months after hospital discharge.

In a prospective cohort study of 243 patients with delirium and 118 controls, delirium was associated with a twofold increase in mortality during a 12-month period following hospitalization (HR 2.11, 95% CI 1.18–3.77).[145] The 1-year mortality rate associated with delirium is 40–63%.[108,145] It is likely that similar outcomes could be expected in patients with drug-induced delirium.

Delirium was associated with an increased risk of in-hospital mortality (OR 1.49, 95% CI 1.08–2.08) in 11,079 patients hospitalized in a referral coronary care unit. In addition, the 1-year mortality among patients with delirium who survived to be discharged from the coronary care unit was also increased (HR 1.46, 95% CI 1.12–1.87).[146]

Delirium has been reported to be responsible for 49% of all hospital days for elderly patients and accounts for an estimated $38–152 billion in annual healthcare expenditures.[110,147] Daily costs were 2.5 times higher in delirium survivors compared to those who did not develop delirium ($461 ± $570 versus $166 ± $570, $p < 0.001$). Prolonged hospital stays account for a portion of these costs, but expenses are compounded by the need for rehabilitation, long-term care, and home healthcare.[132,147]

PREVENTION

There are few studies regarding primary prevention of drug-induced delirium.[132,148] However, methods of prevention of delirium in general may also be effective for prevention of drug-induced delirium (**Table 15-7**). A prospective, controlled trial was conducted in which standardized protocols were implemented for managing specific risk factors for delirium, such as cognitive impairment, sleep deprivation, immobility, visual and hearing impairments, and dehydration in a group of hospitalized patients.[132] Risk factor management in the treatment group reduced the incidence of delirium compared to that in the control (usual care) group (9.9% versus 15%, $p = 0.02$). Risk factor management was also associated with significantly fewer days of delirium and a smaller number of delirium episodes. Those in the risk factor management group that were most adherent to the prevention protocol carried a significantly lower risk of delirium (adjusted OR 0.69, 95% CI 0.56–0.87).[149] These techniques for the prevention of delirium may also be applied to those at risk for the development of drug-induced delirium.

Table 15-7 Approaches to Help Prevent Drug-Induced Delirium

- Avoid anticholinergic, sedative/hypnotic, and opioid medications in the elderly

- Obtain a careful medication history and perform periodic reviews of all drug therapy
- Perform a brief mental status exam on acutely ill patients at admission to assist in the detection of drug-induced delirium
- Avoid medications known to cause drug-induced delirium

Antipsychotic agents have been used to prevent delirium in postoperative patients. Some studies found a decreased incidence of delirium associated with prophylactic antipsychotic administration while others did not.[150-156] Given the conflicting evidence, the use of prophylactic antipsychotic therapy to prevent delirium cannot be recommended.[157] The prophylactic use of acetylcholinesterase inhibitors has also been studied in postoperative delirium patients, but this practice was found to be ineffective in preventing delirium and cannot be recommended.[158-161]

Melatonin has been evaluated for the prevention of postoperative delirium.[162-164] Hanania and Kitain reported the first successful use of melatonin in a nondemented patient with a history of postsurgical delirium.[162] Sultan evaluated the incidence of delirium in a randomized controlled trial in 222 patients receiving hip arthroplasty. Melatonin 5 mg was administered at bedtime on the night before surgery, and another 5 mg was given 90 minutes prior to surgery. Melatonin prophylaxis was associated with a lower risk of delirium (10%) compared to that in the control group (33%).[163] Al-Aama and colleagues evaluated the use of low-dose melatonin in a randomized, double-blind, placebo-controlled trial of 145 patients. Patients received melatonin 0.5 mg or placebo at bedtime for 14 days or until discharge. Patients receiving melatonin had a lower risk of delirium (12% versus 31%, $p = 0.014$).[164]

Ramelteon, a synthetic analog of melatonin and a melatonin (MT)1 and MT2 receptor agonist, has also been evaluated for the prevention of delirium.[165] Hatta and colleagues conducted a multicenter trial in 67 elderly hospitalized patients who were randomized to receive ramelteon 8 mg or placebo at bedtime for 7 days. Ramelteon was associated with a lower risk of delirium (3%) compared to placebo (32%).[165]

Nursing staff on an orthopedic unit were educated regarding the appropriate use of pharmacological and nonpharmacological interventions to prevent and treat delirium.[166] Suggestions regarding medication use included avoiding or minimizing the use of routine anticholinergics to prevent/treat nausea, prescribing morphine in the lowest doses for the shortest possible duration after surgery, and using antipsychotic agents for management of psychotic symptoms of delirium. Medication use was evaluated in the 6 months prior to and after the education session. There was a significant decrease in the use of anticholinergic medications, but the use of opioids and antipsychotics did not change significantly. Data regarding the rates of delirium were incomplete. Effective treatment of pain with opioids led to a reduced risk of development of delirium (OR 0.4, 95% CI 0.2–0.7).[102]

A large randomized controlled trial of a computerized system to identify medications that may contribute to delirium risk and trigger a pharmacist review of patients' medication regimen reported a decrease in delirium incidence (12-month HR 0.42, 95% CI 0.34–0.51) but no significant reduction in falls, hospital admission rate, or mortality.[167]

Because delirium is likely the result of multiple issues, including drugs, management of nondrug risk factors is important for the prevention of drug-induced delirium. Wherever possible, anticholinergic, hypnotic/sedative, and opioid medications should be avoided in elderly patients.[6] A careful medication history should be obtained from patients at risk and periodic reviews of all drug therapy should be performed. All elderly patients who present with an acute illness should be screened for the presence of drug-induced delirium.

MANAGEMENT

Principles of management of drug-induced delirium are presented in **Table 15-8**. Management of drug-induced delirium requires that clinicians recognize the presence of delirium and consider that it may be caused by drugs.[5,6] This can be extremely difficult, particularly in intubated patients in the ICU or those with underlying dementia.[168,169] The most critical step in the diagnosis is a careful medication history. Clinicians must carefully consider any new medications, including nonprescription and herbal and complementary medicines that the patient is taking, and the time to onset of signs and symptoms. Other steps in diagnosis include a physical examination and a toxicology screen, which may help in identifying the drug(s) involved. Determination of serum concentrations of suspected drugs may be helpful; however, some agents may cause drug-induced delirium even at therapeutic concentrations.[2,5] When a particular medication is determined to be the causative agent, therapy should be discontinued or the dose should be reduced whenever possible.[121] A drug that is less likely to cause delirium should be substituted if possible.[2]

Table 15-8 Management of Drug-Induced Delirium

- Identify the causative agent
  - Medication history
  - Physical examination
  - Plasma concentrations
  - Toxicology screen

- Discontinue or reduce the dose of the causative agent; substitute with another drug that does not cause delirium if possible
- Identify and eliminate any other contributors of the drug-induced delirium
- Use a specific antidote (e.g. flumazenil, naloxone) if available
- Use nonpharmacological methods
    - Provide support and orientation
    - Provide an unambiguous environment
    - Maintain competency
- Use drug therapy
    - Atypical antipsychotics
    - Benzodiazepines
    - Haloperidol
    - Melatonin agonists

Management of drug-induced delirium should include supporting and maintaining basic vital functions, including adequate oxygenation, hydration, nutrition, and body temperature. Specific pharmacological and/or physiological precipitants should be identified and discontinued/reversed whenever possible. After treatment is initiated, careful monitoring for signs and symptoms of recovery as well as for treatment-associated adverse effects is important. Any medications used in the treatment of drug-induced delirium should be tapered to discontinuation as soon as possible after recovery to minimize risk of further complications.[121] Care should be taken to prevent dehydration, falls, decubitus ulcers, and aspiration during management of these patients.[101]

Management of drug-induced delirium can include both pharmacological and nonpharmacological treatments.[6] Basic nonpharmacological interventions should always be initiated first because of the ease with which they can be implemented and their proven efficacy.[149] Nonpharmacological approaches to managing delirium include ensuring that patients have their eyeglasses, hearing aids, and dentures, arranging all treatments to be completed during the daytime to permit the maximum amount of sleep at night, reducing nighttime noise, placing familiar objects from home in the room, ensuring clear and concise communications, and encouraging patients to participate in their care and perform their own activities of daily living. The use of physical restraints should be avoided unless patients are likely to harm themselves or others, as deaths have been reported in association with their use.[2,5,170] Constant staff observation in a specialized delirium unit or observation by a sitter or family member is preferable to physical restraint.[169] Often, discontinuation of the causative agent alone is not sufficient, and drug therapy must be used to control symptoms of agitation and psychosis after nonpharmacological measures have been implemented.[6,171]

Psychotropic agents, typical and atypical antipsychotics, and benzodiazepines are the most frequently prescribed classes of medication for the management of delirium. Guidelines from the American Psychiatric Association and NICE recommend psychotropic agents as adjunctive therapy.[2,135] However, these drugs have also been linked to the development of delirium.[103] There are no medications that are approved by the U.S. Food and Drug Administration for the management of drug-induced delirium. Psychotropic agents should be considered after nonpharmacological measures have been implemented, suspected offending drug(s) have been discontinued, and when control of severe agitation is required for the patient's safety or for the safety of others.

Various medications have been utilized for the management of patients with nondrug-induced delirium. However, there is a paucity of evidence supporting the use of medications for the management of drug-induced delirium except where specific antidotes are available (such as naloxone). It seems reasonable, therefore, to discuss literature pertaining to nondrug-induced delirium in this section.

Benzodiazepines may be considered for the treatment of drug-induced delirium, particularly in hyperactive or agitated patients.[172] However, there is little evidence to support the use of benzodiazepines as monotherapy. One study comparing haloperidol, chlorpromazine, and lorazepam in patients with acquired immune deficiency syndrome and delirium reported that lorazepam was less effective than either antipsychotic drug.[168] It is appropriate to initiate benzodiazepine therapy in cases of delirium associated with alcohol or sedative withdrawal or in combination with an antipsychotic agent such as haloperidol when a patient cannot tolerate increases in antipsychotic doses.

Lorazepam is the most commonly used benzodiazepine in patients with delirium because of its rapid onset of action, short half-life, and availability in various dosage forms.[171] This drug is relatively safe for use in patients with hepatic dysfunction, as it has no active metabolites.[172] Lorazepam can be administered orally, intramuscularly (IM), or intravenously (IV) in doses ranging from 0.5 to 2 mg.[169] The dose can be repeated or doubled every 30–60 minutes, depending on the degree of agitation and sedation. Diazepam is recommended as an alternative to physostigmine in patients with anticholinergic toxicity because of its longer duration of action and more favorable adverse effect profile.[6] Haloperidol and phenothiazines should be avoided in this situation.

When benzodiazepines are administered parenterally, they may cause respiratory depression and arrhythmias, and therefore cardiopulmonary function must be monitored.[171] There is also the potential for the occurrence of a paradoxical reaction, in which the patient becomes more agitated with continued benzodiazepine administration. Paradoxical reactions tend to occur more often in the elderly, in those with liver dysfunction, and in patients with low plasma albumin concentrations. Caution should be exercised when using benzodiazepines as they may worsen delirium and cause excessive sedation in some patients.[173]

In a small case series, melatonin 2 mg was administered to two postoperative patients for 3–4 nights. One patient received melatonin for the prevention of delirium and the other for treatment of delirium. In both cases, melatonin effectively reduced the severity of delirium symptoms or prevented delirium. No adverse events were reported.[161] Ramelteon has also been reported to be effective for management of a case of hypoactive delirium.[174]

Haloperidol is the most widely used antipsychotic medication for the symptomatic management of delirium, despite few prospective studies of its effectiveness for agitation and hallucinations in this setting. Haloperidol offers several advantages over the low-potency antipsychotics, including a relative absence of anticholinergic activity, alpha adrenergic blockade, and sedation.[6,172] In nonelderly patients, oral haloperidol doses of 2 mg may be administered for mild agitation, 5 mg for moderate agitation, and 10 mg for severe agitation.[175] In elderly patients, recommended oral haloperidol doses are 0.5 mg for mild agitation, 1 mg for moderate agitation, and 2 mg for severe agitation.[176] Response may occur within 30–60 minutes. The dose may be repeated every 30–60 minutes until the patient is sedated or calm. In some cases, the dose may be doubled until the agitation is controlled. Haloperidol therapy can be continued on a tapering schedule for 3–5 days.[175] The goal is to use the lowest possible haloperidol dose for the shortest possible duration.

In cases in which agitation is severe, the patient is at serious risk of self-injury or is unable or unwilling to take medications orally, haloperidol may be administered IM or IV.[171] Doses vary greatly, from as low as 0.25 mg IM or as high as 10 mg in a single IV dose. A continuous IV infusion of haloperidol may be administered at rates ranging from 2–10 mg/hr.[177] IV administration of haloperidol has been shown to produce a lower incidence of extrapyramidal adverse effects, presumably due to lower concentrations of the pyridinium metabolite; however, IV haloperidol is associated with a risk of prolongation of the corrected QT (QTc) interval and, in some cases, torsades de pointes.[171,178] The maximum daily IV dose should be limited to <35 mg.[179] Patients receiving treatment with IV haloperidol should undergo a baseline electrocardiogram for determination of the heart rate–corrected QT (QTc) interval. Prolongation of the QTc interval to >0.45 seconds or more than 25% above baseline is cause for concern, and the relative risks and benefits of continued therapy must be carefully considered.

The use of high-dose haloperidol for the treatment of delirium is not without controversy. Dopamine D_2 receptor blockade in the mesolimbic region is believed to be the primary mechanism of action; a threshold of 60% of D_2 receptor blockade is necessary for antipsychotic effects. Some argue that very high doses of haloperidol are unlikely to be more effective than lower doses, because 53–85% of D_2 receptors are occupied by haloperidol at doses of 2–20 mg/day.[180] Therefore, large doses should offer no additional benefit, with the potential for a higher incidence of adverse effects. In fact, there are numerous reports of extrapyramidal symptoms (EPS) including pseudoparkinsonism, acute or tardive dystonia, dyskinesias, and akathisia associated with high-dose IV haloperidol or withdrawal from haloperidol therapy.[181,182] Worsening symptoms may be the result of EPS, especially akathisia, which often goes unrecognized and is sometimes inappropriately managed by increasing haloperidol doses.

Some clinicians prefer to use droperidol in the critical care setting, as it is a more potent, rapid-acting antipsychotic that is more sedating than haloperidol and may be associated with a lower incidence of extrapyramidal effects.[183] Bolus IV injections of droperidol have been associated with hypotension, tachycardia, and torsades de pointes.[183] Baseline QTc interval assessment and cardiac monitoring are necessary when administering high doses of droperidol as prolongation of the QTc interval and torsades de pointes can occur. This drug should be reserved for use only in the ICU setting, where patients are closely monitored and resuscitation equipment is immediately available.

A psychiatric consultation service's experience with the use of thiothixene for treatment of delirium was reviewed in a case series. Hospital records were reviewed over a 32-month period to assess response and adverse effects. Resolution or improvement of delirium was documented in 78% of patients and tolerability was documented in 82% of patients.[184]

Newer antipsychotic agents including aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone have been reported to be effective for the management of delirium. The use of aripiprazole for the management of delirium was reported in a small case series of two patients.[185] One patient's MMSE score improved from 5 to 28, while his DRS score decreased from 28 to 6. The second patient's MMSE score improved from 7 to 27 while her DRS score decreased from 18 to 6. In another series, 12 of 14 patients with delirium treated with aripiprazole demonstrated a greater than 50% reduction in the DRS score, while 13 showed improvement on the Clinical Global Impressions (CGI) scale scores.[186] There was a low incidence of adverse effects. Aripiprazole (mean daily dose 18.3 mg) was also evaluated in 21 hospitalized patients with cancer to determine response based on delirium subtypes. Patients with hypoactive delirium had a 100% resolution rate compared to 58% in patients with hyperactive delirium. No clinically significant side effects were noted.[187] Patients who received aripiprazole for the treatment of delirium (n = 21) were compared to 21 case-matched patients treated with haloperidol. The overall delirium resolution rates were similar in the two groups. In patients with hypoactive delirium, the resolution rates were 100% in the aripiprazole group and 78% in patients receiving haloperidol. For patients with hyperactive delirium, the resolution rates in the aripiprazole and haloperidol groups were 58% and 75%, respectively.[188]

Olanzapine has been reported to be effective for delirium in several clinical trials. One study enrolled medically ill patients (mean age = 46 years).[189] The mean maximum dose of olanzapine was 8.8 mg/day and the mean time to response was 3.8 days. In another study, patients with cancer (mean age = 61 years) were enrolled.[190] The mean maximum dose was only 6.3 mg/day. Approximately 76% of patients responded within 4–7 days; however, patients ≥70 years of age had a lower response rate of 42%. Sipahimalani and Masand conducted a retrospective medical record review of 22 mixed medical-surgical patients.[191] Five of 11 patients treated with olanzapine (mean dose 8.2 mg daily) showed a significant improvement in their DRS score compared to 6 of 11 patients treated with haloperidol. In a prospective, randomized, single-blind study, the efficacy of therapy with olanzapine ($n = 28$) was compared with that of haloperidol ($n = 45$) in a mixed group of critically ill medical-surgical patients.[192] Delirium index scores improved similarly in both groups, and the need for rescue therapy did not differ between groups. Six patients receiving haloperidol experienced mild EPS compared with none in the olanzapine group. Elsayem and colleagues conducted a prospective unblinded study to evaluate the effectiveness of subcutaneous olanzapine for the management of hyperactive or mixed delirium in 24 patients with advanced cancer. Patients received olanzapine 5 mg or 10 mg subcutaneously every 8 hours for 3 days. Efficacy was observed in 9 of 24 (37.5%) of patients. No injection site reactions were reported, but adverse effects (hypotension, agitation, diabetes insipidus, and seizures) were observed in four patients.[193]

Several case reports indicate that quetiapine may be a reasonable option for management of delirium.[194-196] Sasaki et al. reported the effect of quetiapine therapy in 12 patients with delirium of multiple etiologies.[197] Patients were treated for an average of 4.8 days ± 3.5 days with a flexible dose of quetiapine (mean maximum dose was 63.5 mg/day). Delirium rating scale scores improved significantly, and no patient experienced significant adverse events. In a retrospective review of the medical records of 22 mixed medical-surgical patients, quetiapine (median dose = 211 mg daily) was as effective as haloperidol in improving DRS score by more than 50% from baseline.[198] One patient receiving quetiapine experienced mild-to-moderate sedation and two patients receiving haloperidol developed EPS. In another study, the efficacy of therapy with quetiapine at doses of 25–100 mg daily for 7 days was assessed in 22 patients with delirium.[199] The DRS and CGI scores on days 2–7 were significantly lower than those on day 0. Two patients (9.1%) developed mild tremor. Tahir and colleagues conducted a randomized, double-blind, placebo-controlled trial evaluating the effectiveness of quetiapine in 42 patients with delirium. The primary outcome measure was the DRS Revised 98 (DRS-R-98). No differences at individual time points (day 3 and day 10) were statistically significant.[200] Devlin and colleagues conducted a multicenter, prospective, randomized, double-blind, placebo-controlled study to evaluate the efficacy of quetiapine 50 mg every 12 hours for management of delirium in 36 critically ill patients. Patients who received quetiapine spent less time in delirium compared to those in the placebo group (36 hours versus 120 hours, $p = 0.006$) and less time agitated (6 hours versus 36 hours, $p = 0.02$). Mortality and length of ICU stay were similar between the groups.[201] Quetiapine was compared to haloperidol in a prospective, double-blind, randomized controlled trial of 52 medically ill patients with delirium. Patients were randomized to receive quetiapine 25–100 mg/day ($n = 24$) or haloperidol 0.5–2 mg/day ($n = 28$). The mean change in DRS-R-98 score for quetiapine (–22.9) was not significantly different from that in patients receiving haloperidol (–21.7; $p = 0.59$).[202]

Risperidone at mean doses of 0.75–1.7 mg daily has been reported to be effective for the management of delirium.[203,204] In an unblinded study, 64 medically ill hospitalized patients with delirium received oral risperidone in daily doses of 1.85–2.97 mg (mean daily dose 2.6 mg ± 3.3 mg).[205] Risperidone was effective in 58 of 64 patients and significantly improved all symptoms measured by DRS, Positive and Negative Syndrome Scale, MMSE, and CGI during a period of 7 days. The comparative efficacy of risperidone and haloperidol for treatment of delirium was assessed in a prospective, randomized, double-blind study of acutely ill inpatients.[206] The MDAS improved significantly in both groups at 7 days; there was no significant difference in efficacy between the groups. In another study, the relationship between response and genetic polymorphisms in the dopamine transporter was studied in 42 patients treated with either haloperidol or risperidone for management of delirium.[207] There was no difference in efficacy between the groups, indicating that dopamine transporter polymorphisms did not significantly influence the effects of the antipsychotics. In a randomized, double-blind study of 126 patients undergoing cardiac surgery with cardiopulmonary bypass, patients were randomly assigned to receive risperidone 1 mg or placebo sublingually.[153] The incidence of postoperative delirium was significantly lower in the risperidone group. Miyaji et al. compared the adverse effects of risperidone with those of haloperidol in a retrospective study of 266 Japanese inpatients treated for delirium; the incidence of adverse effects was significantly lower in risperidone-treated patients.[208] Kim and colleagues conducted a randomized, comparative clinical trial of risperidone and olanzapine in 32 patients with delirium. The mean initial dose and the mean last dose in the risperidone group were 0.6 mg and 0.9 mg, respectively, and 1.8 mg and 2.4 mg, respectively, in the olanzapine group. The primary outcome measure was the DRS-R-98. There was no significant difference in response rate (≥50% reduction from baseline in the DRS-R-98 score) between the risperidone and olanzapine groups (64.7%, 73.3%; $p = 0.71$).[209] Kishi and colleagues evaluated the use of risperidone (mean dose 1.4 mg/day) in 29 patients with cancer and delirium. DRS-R-98 scores improved in 23 of 29 (79%) patients, showed no change in 4 of 29 (14%), and worsened in 2 of 29 (7%). The response rate (defined as a 25% reduction in DRS-R-98 score) was achieved in 14 of 29 (48%) of risperidone-treated patients.[210]

Ziprasidone has also been used for the treatment of delirium.[211,212] This drug is associated with a low risk of sedation and EPS. In a case report in which ziprasidone was administered for delirium, the drug was effective; however, the patient exhibited QTc interval prolongation requiring drug discontinuation.[211] Girard and colleagues conducted a multicenter, randomized, double-blind, placebo-controlled trial in 101 mechanically ventilated ICU patients. Patients were randomized to receive haloperidol, ziprasidone, or placebo every 6 hours for up to 14 days. The primary outcome was the number of days patients were alive without delirium or coma. Patients in the haloperidol group spent a similar number of days alive without delirium or coma (median interquartile range 14 days) as the patients in the ziprasidone (15) and placebo groups (12.5; $p = 0.66$).[213]

Overall, haloperidol and atypical antipsychotics appear to be equally efficacious for the treatment of delirium in acutely ill hospitalized patients.[214-219] However, this statement must be tempered by the fact that large randomized placebo-controlled trials supporting the efficacy of these agents for the treatment of delirium are lacking. In addition, all antipsychotic agents include a boxed warning in their labeling regarding an increased risk of mortality in elderly patients treated for dementia-related psychosis. Clinicians should weigh the benefits and risks associated with antipsychotic drug therapy prior to prescribing these agents for the management of drug-induced delirium.[220] Further studies are required to determine the role of antipsychotics in the management of delirium.

Pharmacological strategies for management of drug-induced delirium should be implemented after nonpharmacological measures have been attempted, suspected offending drug(s) have been discontinued, when control of severe agitation is required for the patient’s safety or for the safety of others, and when psychosis is present.

INFORMATION FOR PATIENTS

Patients taking medications implicated in causing delirium and their caregivers should be instructed to be vigilant for early signs and symptoms of the disorder. In addition, they should be taught about available nonpharmacological treatment approaches and instructed to implement these measures should the patient develop signs or symptoms.[6] Early recognition and intervention may prevent or ameliorate this disabling condition.

CHAPTER 16

Sleep Disorders

Lisa L. Forsyth

Sleep is essential, comprising approximately one third of life.[1] Drug-induced sleep disorders, such as insomnia, may be reported as difficulty falling asleep, not feeling rested despite adequate time to sleep, and/or daytime sleepiness. Although sleep disturbances may be caused by a variety of medical or psychiatric conditions, drugs always must be carefully considered as a potential cause of these symptoms.

CAUSATIVE AGENTS

Drugs that affect the central nervous system may cause altered patterns of sleep and wakefulness. These effects may be present immediately upon initiation of therapy or following withdrawal of therapy. In addition, drugs may exacerbate primary sleep disorders. Drugs that are reported to cause sleep disorders are listed in **Table 16-1**.[2-60]

EPIDEMIOLOGY

Insomnia is reported in approximately one third of adults in the United States and is considered to be a serious problem in about 50% of those afflicted.[61-63] The overall incidence of drug-induced sleep disturbances in the general population is not known, but individual agents are associated with incidences ranging from 1% to 55% (Table 16-1).[64]

MECHANISMS

Humans, along with most mammals, undergo two phases of sleep: rapid eye movement (REM) and nonrapid eye movement sleep (NREM).[65] NREM sleep is subdivided into stages 1 through 4. A full cycle of NREM and REM sleep requires approximately 90 minutes; and this cycle is repeated approximately four to six times throughout the night. Researchers do not yet fully understand all the functions of REM and NREM sleep and their relationship to the symptoms of sleep disturbance. Elderly individuals experience alterations in sleep patterns manifested typically as decreases in REM, stages 3 and 4 of NREM, and total sleep time. These changes have been found to correspond to added awakenings and total time spent awake at night.[66-68]

Several neurotransmitters are responsible for the sleep cycle.[69] The neurochemistry responsible for sleepiness and wakefulness has not been fully elucidated, and it is unknown whether one or more neurotransmitters is responsible for sleeping or awakening.[70] A primary function of norepinephrine-containing neurons is to regulate the sleep pattern. Wakefulness is believed to be mediated by norepinephrine, dopamine, acetylcholine, and serotonin.[71] Hypocretin (orexin) is a neuropeptide secreted by the hypothalamus and believed to promote sleep.[69] Melatonin is secreted by the pineal gland in conjunction with dark-light cycles and may promote sleep.

Table 16-1 Agents Implicated in Drug-Induced Sleep Disorders

Drug	Incidence	Level of Evidence[a]
α_2 AGONISTS[5,6]	30–75%	B
Clonidine	Sedation, nightmares	
Methyldopa	Insomnia, sedation, nightmares	
ANTICONVULSANTS[7-12]		
Carbamazepine	NK	C
Felbamate	8.6%	B
Lamotrigine	NK	C
Phenytoin	NK	C

ANTIPARKINSONIAN AGENTS[13-19]		
Amantadine	14%	B
Entacapone	30%	B
Levodopa–carbidopa	75%	B
Pergolide, bromocriptine	42%	B
Selegiline	10–32%	B
Trihexyphenidyl, benztropine	NK	C
β-BLOCKERS[5,20-22] **(lipophilic: propranolol, timolol)**	2–4.3%	B
β-BLOCKERS WITH α-BLOCKING ACTIVITY[23,24]		B
Carvedilol	3–11%	
Labetalol	1–4%	
MAO INHIBITORS[40]		
Phenelzine, tranylcypromine	NK, daytime sleepiness	B
SNRIs		
Desvenlafaxine[41]	6–15%	B
Duloxetine[42,43]	12.6%	B
Venlafaxine[25,44-47]	Insomnia 8% Sedation 13–31%	B
SSRIs		
Citalopram[48]	NK	C
Escitalopram[43]	4.9%	B
Fluoxetine[25,48-51]	Insomnia 5–19% Daytime sedation 5–18%	B
Fluvoxamine[25,49,52]	Insomnia 10–15% Daytime sedation 14–26%	B
Paroxetine[25,49,51,53,54]	Insomnia 8–14% Daytime sedation 2–21%	B
Sertraline[25,48]	Insomnia 7–16% Daytime sedation 7–13%	B
STATINS		
Atorvastatin[56]	3%	C
Lovastatin[57,58]	0.5–1%	C
MISCELLANEOUS		
Alcohol[2]	NK	C
Bupropion (Naltrexone–bupropion)[25,26]	5–19% 9.2%	B C
	12–70%	B

Corticosteroids[27-38]		
Locaserin[39]	3.5%	C
Stimulants[30,59,60] (e.g., caffeine, cocaine, methylphenidate, theophylline)	46–55%	B

MAO = monoamine oxidase, NK = not known, SNRI = serotonin-norepinephrine reuptake inhibitor, SSRI = selective serotonin reuptake inhibitor.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

There are three primary mechanisms of drug-induced sleep disturbances (**Table 16-2**).[72-75] First, the desired effects of a drug may affect the neurotransmitters or receptor sites responsible for sleepiness. Second, the sedative effects of drugs used to treat insomnia may carry over into the daytime hours. Third, withdrawal of therapy may produce a sleep disturbance.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Patients suffering from sleep disturbance often report an inability to fall asleep, to maintain sleep, or both, or of not feeling rested after having time to sleep.[72-75] Often these complaints are followed by daytime sleepiness and an inability to concentrate. The common signs and symptoms of sleep disorders are listed in **Table 16-3**. A number of medical and psychiatric conditions (**Table 16-4**) are known to affect sleep, and these must be considered when evaluating a patient for a possible drug-induced sleep disorder.[73,74] Polysomnography (PSG) is an assessment of electrophysiologic parameters during sleep and includes an electroencephalogram, electrooculogram, and electromyelogram.[74] Other measures of sleep include sleep latency (time to fall asleep), REM latency (time to first REM sleep), number of awakenings, and the number of stage shifts during sleep.[65,74]

The effects of drugs on sleep are often identified and characterized based on subjective data, PSG measures, objective evidence of sleepiness and alertness from a Multiple Sleep Latency Test (MSLT), wrist actigraphy, and/or by objective performance data.[65,69] The MSLT measures the time to fall asleep in order to evaluate excessive daytime sleepiness. Wrist actigraphy determines the sleep time by measuring wrist movements. Evidence of sleep disturbance on the PSG does not always correlate with patients' subjective complaints.[72-74] Bupropion and venlafaxine have been reported to induce insomnia in as little as 4 days and up to 4 weeks, respectively, following initiation of therapy.[64,75] The time of onset of insomnia associated with the other agents listed in Table 16-1 is highly variable.

Patient assessment should begin with a medication history and physical examination. Further psychiatric assessment should be undertaken if indicated. When a drug-induced sleep disorder is suspected, patients should be questioned regarding the use of medications known to affect neurotransmitters, the frequency and timing of drug administration, and any history of recent discontinuation of medication.[72] The utility of sleep studies in the diagnosis and characterization of drug-induced sleep disturbance has not been determined.

Table 16-2 Mechanisms of Drug-Induced Sleep Disorders

Drug	Mechanism (neurotransmitter/PSG data)
Alcohol[2-4]	Mechanism unknown, occurs upon withdrawal ↑W, ↓TST
α_2 agonists[5,6]	α_2 receptor agonism No PSG studies available
Antiparkinson agents[13-19]	Effect on various neurotransmitters specific to each drug ↑W, ↓TST
β-blockers[5,20-22]	β-adrenergic inhibitor, lipophilic agents ↑W, ↓TST, ↑S1, ↓REM
β-blockers with α-blocking activity[23,24]	β- and α-antagonism No PSG studies available
Bupropion[25,26]	DA uptake inhibition Minimal PSG data
Corticosteroids[27-38]	Mechanism unknown ↑W, ↑S2, ↓REM
MAO inhibitors[40]	Inhibits MAO enzyme that degrades NE, 5-HT, DA ↓REM, ↑W, ↓TST
SNRIs[25,41-47]	5-HT, NE uptake inhibition, weak affects on DA uptake; ↑W, ↓TST
SSRIs[25,43,48-54]	5-HT uptake inhibition In general ↑W, ↓TST
Statins[56-58]	Mechanism unknown Minimal PSG data, ↑W observed
Stimulants[30,59,60]	Release of various neurotransmitters ↑W, ↓TST

5-HT = 5-hydroxytryptamine (serotonin), DA = dopamine agonists, MAO = monoamine oxidase, NE = norepinephrine, PSG = polysomnography, REM = rapid eye movement, SNRI = serotonin-norepinephrine reuptake inhibitor, SSRI = selective serotonin reuptake inhibitor, S1 = stage 1 sleep, S2 = stage 2 sleep, TST = total sleep time, W = wakefulness.

Table 16-3 Signs and Symptoms Associated with Drug-Induced Sleep-Disorders[72,74]

- Inability to fall asleep
- Inability to maintain sleep
- Not feeling rested following adequate sleep duration
- Excessive daytime sleepiness
- Poor cognitive performance
- Lack of concentration

RISK FACTORS

Specific risk factors for drug-induced sleep disorders have not been definitively elucidated. Older age (beginning in middle-aged adults) and female sex are known risk factors for insomnia, but it is not known if they also are risk factors for drug-induced sleep disorders.[64] Most studies that have attempted to evaluate drug effects on sleep have been conducted in healthy individuals, primarily men, who may respond differently than patients with disease.[64] In addition, the treatment population may already have sleep disturbances or impaired daytime performance prior to the initiation of drug therapy. Both age and drug dose contribute to the frequency of sleep disturbances associated with β-blockers.[64] Potential risk factors for drug-induced sleep disorders are listed in **Table 16-5**.

Table 16-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Sleep Disorders[73,74]

Medical

Neurologic

- Delirium
- Epilepsy
- Parkinson disease

Respiratory

- Asthma
- Obstructive sleep apnea

Cardiovascular

- Arrhythmias
- Heart failure

Gastrointestinal

- Gastroesophageal reflux
- Peptic ulcer disease

Endocrine

- Diabetes mellitus
- Hyperthyroidism

Chronic pain

Pregnancy

Psychiatric

Mood Disorders

- Depression
- Mania

Anxiety Disorders

- Generalized anxiety disorder
- Obsessive-compulsive disorder
- Panic

Situational

- Work or financial
- Interpersonal conflict
- Major life events
- Jet lag
- Shift work

Table 16-5 Risk Factors for Drug-Induced Sleep Disorders[64,74]

- Female sex
- Older age
- Concomitant therapy with ≥2 agents with central nervous system effects
- Drug interaction

In addition to directly causing sleep disturbances, drugs may exacerbate symptoms and increase the risk of primary sleep disorders. One example is obstructive sleep apnea, which is characterized by loud snoring and gasping or apneic episodes during sleep. Patients with sleep apnea typically experience excessive daytime sleepiness and poor performance. A patient’s apneic episodes may worsen in association with the use of sedative/hypnotic agents, and daytime symptoms may become more severe.[64,72] In addition, the menopausal symptom of “hot flashes” during nighttime hours has been reported as a cause of insomnia following the discontinuation of hormone-replacement therapy.

MORBIDITY AND MORTALITY

Sleep disorders may impair quality of life beyond excessive daytime sleepiness. It has been reported that those who suffer insomnia receive fewer career promotions, demonstrate poor productivity, and have a higher rate of absenteeism.[74,75] In addition to poor performance during the daytime hours at work, there is an increased risk of motor vehicle accidents reported in individuals experiencing insomnia. Nearly 70 million Americans suffer from a sleep disorder, which may have negative consequences on their overall health and well-being.[76] The total cost of insomnia in 2011 was estimated at nearly $63 billion.[75] It is difficult to quantify the financial burden of insomnia because patients often have other comorbidities that contribute to the expenses.[76] Healthcare costs are up to 60% higher in patients with insomnia.[77]

Obstructive sleep apnea has been associated with hypertension, the primary mechanism of which is sympathetic hyperactivity.[78] In addition, sleep deprivation experienced for one night has been linked to hypertension in the ambulatory care setting.[79,80]

Decreased sleep duration may impair glucose tolerance and insulin sensitivity.[81-84] Insulin resistance, like hypertension, may be linked to the increased sympathetic outflow associated with reduced sleep duration. One investigation that spanned 10 years suggested that sleep duration of 5 hours or less may be a significant risk factor for the development of diabetes.[81] Currently, there are no data regarding the incidence of morbidity or mortality directly associated with drug-induced sleep disorders.

PREVENTION

Prevention of drug-induced sleep disorders requires a better understanding of the basic functions and different stages of sleep. Basic and clinical research is necessary to allow clinicians to anticipate possible sleep disturbances based on the pharmacological properties of specific drugs. Nonpharmacological measures to improve sleep hygiene (**Table 16-6**) are useful and have been shown to improve sleep patterns in 70–80% of patients.[85]

Table 16-6 Approaches to Help Prevent Drug-Induced Sleep Disorders[65,85]

Sleep hygiene

- Establish a regular bedtime and wake up time including weekends
- Sleep only as much as necessary
- Go to bed only when sleepy, using the bed only for sleep and intimacy

- Avoid long periods of wakefulness while in bed
- Avoid trying to force sleep; after 30 minutes, leave the bed to do something relaxing (watch television, listen to music, or read)
- Avoid daytime naps
- Do not take your worries to bed
- Exercise regularly (three to four times weekly); however, exercising near bedtime may cause arousal
- Create comfortable sleeping environment (steady temperature, lack of light source)
- Reduce or discontinue the use of alcohol, caffeine, or nicotine
- Avoid hunger or fullness at bedtime
- Avoid drinking large amounts of liquids in the evening to prevent trips to the restroom at night
- Engage in a relaxing or enjoyable activity before bedtime

Pharmacologic approach

- Discontinue agents with potential to cause drug-induced sleep disturbances when possible
- If unable to discontinue potentially causative agents:
  - o Change time of administration to earlier in the day
  - o Reduce dose to decrease symptoms (e.g., selegiline)

MANAGEMENT

As sleep disturbances may affect all aspects of an individual's life, all symptoms should be investigated carefully. Management of drug-induced sleep disorders requires a thorough understanding of the pharmacology, especially the neurotransmitter activity, of each of the patient's medications. It also is important to consider drug combinations with possible additive central nervous system effects and drug interactions that may potentiate drug effects by altering pharmacokinetics or pharmacodynamics. The first step in management involves discontinuation of agents with potential to cause drug-induced sleep disorders (Table 16-1 and 16-6). The time frame for resolution of symptoms following drug discontinuation is a function of the agent's half-life.

In some cases, such as in patients with seizure disorders, discontinuation of the potentially causative agent is not possible and alternative measures are required. Changing the time of drug administration to earlier in the day may help reduce symptoms for some patients. With some drugs (e.g., selegiline) symptoms are reported most often in association with higher doses, and dose reduction may be helpful.

It is reasonable to employ drug therapy for insomnia when all other measures to resolve a drug-induced sleep disorder have failed. For insomnia requiring short-term treatment, there is no difference in efficacy between benzodiazepines, antidepressants, or sedative-hypnotic agents.[74,85,86] Patients with difficulty falling asleep or with excessive daytime sleepiness may benefit from therapy with a short-acting benzodiazepine such as triazolam or a hypnotic agent such as zolpidem, zaleplon, or eszopiclone.[56,84-87] Patients who are unable to maintain sleep or have trouble awakening may benefit from therapy with an intermediate-acting benzodiazepine such as estazolam or temazepam. The long-acting benzodiazepines (flurazepam and quazepam) may be helpful when there is daytime anxiety in addition to sleep disturbance. There is no rationale, however, for the concomitant use of two benzodiazepines for the treatment of insomnia and anxiety. In all cases, the lowest effective dose should be administered for the shortest possible period of time. Tolerance can develop in as little as 2 weeks with continuous use of some benzodiazepines.[75] One strategy used to help prevent tolerance involves the administration of benzodiazepines for only 3–4 days per week rather than daily.

Two medications recently approved by the U.S. Food and Drug Administration may be effective for treating insomnia: suvorexant and ramelteon. Suvorexant, an orexin antagonist, increases total sleep time by reducing time to sleep onset and awakening after falling asleep.[87] Ramelteon, a melatonin-receptor agonist, modestly improved time to sleep onset but had no effect on total sleep time.[88] There are currently no published data regarding the efficacy of these agents for managing drug-induced sleep disorders.

When long-term treatment of insomnia is required, antidepressants are among potential options.[86] Trazodone may be effective at doses of 50–100 mg for insomnia associated with fluoxetine and bupropion.[89] An advantage of trazodone is its lack of anticholinergic activity. Doxepin has also shown promise in treating antidepressant-induced insomnia and maintains normal nocturnal melatonin secretion.[86] Several other agents, such as antipsychotics (mirtazapine) and melatonin, have been used for the long-term treatment of insomnia but supporting data are limited, and these agents are associated with adverse effects.

Most patients initially seek a nonprescription remedy for the treatment of sleep symptoms. Unfortunately, there are limited data regarding the efficacy of nonprescription drugs.[90] Of the many options available, melatonin is the only agent that has undergone extensive evaluation of its circadian effects and hypnotic properties. Limited and contradictory evidence is available for the efficacy of histamine H_1-receptor antagonists and valerian. Other alternative agents for which some supportive data exist include passionflower, chamomile, St. John’s Wort, kava, wild lettuce, patrinia root, and vitamins and supplements (calcium, vitamin A, nicotinamide, magnesium, and vitamin B_{12}).[90] Potential harm of these agents should be considered as the products are not standardized, which discourages healthcare providers from recommending them for routine treatment.[65]

When a treatment is initiated for a sleep disorder, the lowest effective dose should be prescribed. Ideally, these agents should be used for the shortest period of time possible, but this may not be feasible for those patients requiring a longer duration of therapy. Patients under treatment for drug-induced sleep disorders should be routinely monitored to assess the effectiveness of drug therapy and to ensure the resolution of symptoms.

INFORMATION FOR PATIENTS

Patients who are prescribed medications that are known to cause sleep disorders should be instructed to contact their healthcare provider if they experience difficulty falling asleep, do not feel rested after having adequate time to sleep, or are excessively tired during the day. Sleep hygiene education should be provided to patients to identify opportunities to improve sleep disturbances. Patients should be advised to consult with their physician or pharmacist before beginning treatment with any nonprescription medication to avoid interactions that could precipitate sleep disturbances. Finally, patients should be warned not to change the dose or administration times of prescribed medications without consultation with their physician or pharmacist.

CHAPTER 17

Cognitive Disorders

Michele Y. Splinter

Cognitive function is a multidimensional concept for higher-order mental functions and processes.[1,2] Cognitive domains described in the *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* (*DSM-5*), are perceptual-motor function, language, executive function, learning and memory, complex attention, and social cognition.[3] The *DSM-5* divides the neurocognitive disorders into three syndromes: delirium, mild cognitive disorders, and major cognitive disorders (dementia). Delirium is a disturbance in attention and awareness developing over a short period and is a consequence of another medical condition, substance intoxication or withdrawal, exposure to a toxin, or due to multiple etiologies, and is most often reversible after the insult is removed. Mild and major neurocognitive disorders represent a cognitive decline in performance in one or more cognitive domains and can be due to a number of etiologies including Alzheimer disease, vascular disease, frontotemporal lobar degeneration, and substance or medication use. The ability to live an independent life or not differentiates mild from major neurocognitive disorders.

CAUSATIVE AGENTS

Drugs that have been implicated as causes of cognitive disorders are listed in **Table 17-1**.[4-33] Effects associated with some medications, such as sedation from opiates, are experienced acutely. Cognitive effects of other medications are subtle and are often recognized only with long-term use. An example is slowing of cognitive processing speed in children leading to attention and memory deficits associated with phenobarbital.[34,35]

EPIDEMIOLOGY

It is difficult to determine the relative frequency of drug-induced cognitive disorders because of the diversity of drugs capable of causing cognitive impairment and the divergent demographic characteristics of study populations.[8] In one study, 22% of 229 consecutive hospitalized patients over 70 years of age experienced delirium.[35] Drug toxicity was identified as the most definitive cause of delirium and was the third most probable contributor, after infection and fluid and electrolyte imbalance. In another prospective study, 7% of 1,500 hospital neurologic consultations were for delirium, 17% of which were attributed to drugs.[37]

Table 17-1 Agents Implicated in Drug-Induced Cognitive Disorders

Drug Class/Medication	Incidence	Level of Evidence[a]
Androgen-deprivation therapy[4]	NK	B
Anticholinergics[5,6]	18–20%[b]	A
Antiarrhythmics (amiodarone, digoxin, lidocaine)[7,8]	NK	C
Antibiotics[8,9]	NK	C
Antifungals[8,9]	NK	C
Antiretrovirals[8,9]	NK	C
Anticonvulsants	NK	B
Phenobarbital[10]	NK	B
Topiramate[11,12]	35%[c] 7–71%[d]	A
Valproic acid[13]	22%[e]	B
Antineoplastic agents[14,15]	4–75%[f]	A
Cyclophosphamide, thiotepa, carboplatin[1,7]	25%[g]	A

Antipsychotics[16,17]	NK	B
Antiparkinson agents[7,8,18]	NK	C
Benzodiazepines (chronic)[19]	22.2%	B
Glucocorticosteroids[8]	NK	C
Histamine-2-receptor antagonists[20]	0.2% (outpatient) 1.6–1.9% (inpatient)	B
Interferon alfa[21-24]	30–77%	B
Lithium[25,26]	NK	B
Non-nucleoside reverse transcriptase inhibitors[27,28]	18.9–23%	B
Nonsteroidal anti-inflammatory drugs[29-31]	NK	B
Opioids[32]	20–70%[h]	B
Selective serotonin reuptake inhibitors[33]	0.5%	B

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Elderly.

[c] Healthy volunteers.

[d] Obese children—memory (71%), psychomotor speed (36%), language (29%), attention (29%), visual–spatial perception (14%), and intelligence (7%).

[e] Children of epileptic mothers who took valproate scoring ≤69 on verbal intelligence quotient (IQ).

[f] Varies depending on medication, regimen, population, stage of cancer, domain measured, time of measurement.

[g] High-risk patients with breast cancer receiving high-dose chemotherapy (cyclophosphamide, thiotepa, and carboplatin after receiving standard-dose chemotherapy).

[h] Varies depending on population (healthy, patient with cancer, or patient with nonmalignant pain—and whether tolerant to medication).

In an outpatient study of 308 patients older than 60 years of age with pre-existing global cognitive impairment, 35 (11.4%) experienced adverse drug reactions contributing to cognitive dysfunction.[38] Upon follow-up 1 year after enrollment, medications were determined to be the sole cause of cognitive changes in 10 of these patients, and in the others, cognitive function improved after discontinuation of the offending agent.

Commonly used instruments that can be administered within 10 minutes to screen for decline in cognition include the Mini-Mental State Exam and the Montreal Cognitive Assessment (MoCA).[39,40] Reported incidences of cognitive disorders depend on the cognitive domain investigated and the measurement instrument used.[41] For example, more than 80 instruments have been employed to assess the different domains of cognitive function in patients with cancer. Several challenges to using cognitive assessments in cancer research have been identified, including the fact that baseline data may not reflect function before the cancer diagnosis, moderating variables (education, race, age, sex) may affect comparisons between groups or established norms, tests may be subject to practice and learning effects, and a valid comparison group is difficult to identify because cancer treatment is specific to diagnosis, stage, and biological factors characteristic of the specific malignancy.[1]

Table 17-2 Mechanisms of Drug-Induced Cognitive Disorders

Drug	Mechanisms
Anesthetics[43]	Neuronal apoptosis from activation of caspase and amyloid-β aggregation; tau phosphorylation; alteration of central cholinergic transmission through nicotinic and muscarinic receptors; upregulation of NMDA receptors causing excitotoxicity and apoptosis from calcium influx
Anticholinergics[44,45]	Age-related loss of acetylcholine and cholinergic cell bodies in nucleus basalis of Meynert; accumulation of amyloid-beta peptides in the cortex, hippocampus, and amygdala
Anticonvulsants[34,46,47]	Reduction of neuronal excitability; decrease in the expression of neurotrophins and β-estradiol causing dose-dependent apoptotic neurodegeneration in fetal brains
Antineoplastic agents[48-51]	Leukoencephalopathy, direct cytotoxic effects, cytokine-induced inflammatory response, chemotherapy-induced anemia and menopause; genetic risk factors (low-efficiency efflux pumps, deficits in DNA repair mechanisms), shortened telomere length, and decreased neurotransmitter activity and functional connectivity
Antipsychotics[52]	Decreased cholinergic enzyme choline acetyltransferase; decreased nicotinic and muscarinic acetylcholine receptors due to antagonist activity at dopaminergic-D_2 receptors; decreased nerve growth factor and brain-derived growth factor
Barbiturates[53,54]	Enhancement of GABA, decreased calcium uptake by neuronal membranes depressing excitability; reduction in number of fetal neurons and the length and branching frequency of dendrites
Benzodiazepines[53]	Enhancement of GABA activity
Glucocorticosteroids[55,56]	Hippocampal cell loss
Histamine-2-receptor antagonists[57]	Blockade of histamine-2 receptors in the cerebral cortex and corpus striatum
Interferon alfa[58]	Inhibition of dopaminergic activity
Nonsteroidal anti-inflammatory drugs[30]	Hypersensitivity response types 1 and 3 (aseptic meningitis) Inhibition of lipid beta-oxidation and mitochondrial disarrangement (Reye syndrome)
Opioids[32,59]	Inhibition of the cholinergic system; modulation of behavior of microglia and immune cells that mediate inflammation; apoptosis of microglia and neurons

Selective serotonin reuptake inhibitors[60,61]	Hyponatremia secondary to inappropriate antidiuretic hormone secretion
Tricyclic antidepressants[53]	Anticholinergic and antihistaminic effects

DNA = deoxyribonucleic acid, GABA = gamma-aminobutyric acid, NMDA = *N*-methyl-D-aspartate.

MECHANISMS

Several neuronal processes in the brain are associated with states of awareness.[42] Specific mechanisms of cognitive disorders associated with several classes of medications are summarized in **Table 17-2**.[30,34,43-61]

It has been proposed that neural pathways mediated by acetylcholine regulate conscious awareness and its intensity. Anticholinergic agents are used as antiemetics, antiparkinson agents, and antispasmodics, and have been associated with cognitive impairment.[7,18,62-64] In addition, drugs in many other classes possess anticholinergic properties, including tricyclic antidepressants, antipsychotics, antihistamines, and antiarrhythmics.[7,44] Memory loss in patients with Alzheimer disease or Parkinson disease with prominent dementia has been associated with a significant decline of cortical cholinergic innervation due to cell loss in the nucleus basalis.[65] High-frequency oscillations that unite information related to different aspects of a perceived object from widely distributed cortical neurons appear to emanate from the thalamus.[42] The action of acetylcholine in the cortex and thalamus and the interactions between the neurotransmitters acetylcholine, gamma-aminobutyric acid (GABA), and glutamate appear to be central to the maintenance of conscious awareness. Alzheimer disease is associated with amyloid plaque and formation of neurofibrillary tangles.[66] In a histological study from brains of patients over 70 years of age with Parkinson disease, anticholinergic use for greater than 2 years increased amyloid plaque and neurofibrillary tangle densities by twofold.[66] Authors hypothesized that there was acceleration of β amyloidosis and plaque formation in aging brains in these subjects induced by the antimuscarinic drugs. Rebound insomnia and anxiety have been reported in association with benzodiazepine and barbiturate withdrawal, and hallucinations and delirium have been associated with barbiturate withdrawal.[53] Down-regulation of high-affinity GABA receptors occurs during benzodiazepine and barbiturate therapy, and the withdrawal syndrome probably reflects a state of GABA underactivity in conjunction with a surge in output of excitatory neurotransmitters normally inhibited by GABA. There also appears to be a noradrenergic mechanism contributing to consciousness, as α_2-receptor antagonists and variations in norepinephrine concentrations alter anesthetic dose requirements.[42] In addition, α_2-receptor agonists increase the depth of anesthesia.

Anticonvulsant medications diminish neuronal irritability and therefore may inhibit neuronal excitability and impair cognitive function.[34,46] High serum concentrations of valproate have been shown to affect both function and morphology of the brain, possibly due to interference with pituitary adrenal function, hyperammonemia, or changes in blood–brain barrier permeability.[67] Histologic examination of brains of rats aged 3–30 days who had received phenytoin, phenobarbital, valproate, vigabatrin, diazepam, or clonazepam revealed apoptotic neurodegeneration.[47,54] Anticonvulsants not found to cause apoptosis include carbamazepine, lamotrigine, levetiracetam and topiramate.[68] In addition, anticonvulsants have been implicated in impairing developing brains by diminishing neurogenesis and synaptogenesis.[68]

The hippocampus, which is critical for the formation of new memories, possesses the highest concentration of corticosteroid-binding sites in the brain.[69] Glucocorticoids inhibit glucose transport into cells by 25–30%, thereby accelerating the usual decline in adenosine triphosphate concentrations after ischemia or hypoglycemia.[55] This lessens the cell's ability to inhibit neuronal insults, leading to neuronal death. In several studies involving children with acute lymphoblastic leukemia, those treated with dexamethasone performed less well on cognitive testing than children treated with prednisone.[70,71] It has been hypothesized that dexamethasone may be more neurotoxic than prednisone because of a lesser degree of plasma protein binding and due to the presence of a fluoride atom in its chemical structure.[70] Altered brain membrane lipid content and synaptic transmission in hippocampal neurons have been associated with fluoride anions.[70]

Acute changes in mental status can occur in association with selective serotonin reuptake inhibitors (SSRIs) as a result of hyponatremia due to the syndrome of inappropriate antidiuretic hormone (ADH) secretion.[33,60,61] Increased concentrations of ADH result in the inability of renal tubules to excrete diluted urine, decreasing serum osmolality and serum sodium, resulting in neurological changes that may include lethargy, confusion, seizures, coma, and death.[61] This syndrome may also be caused by other medications, including carbamazepine, oxcarbazepine, tricyclic antidepressants, monoamine oxidase inhibitors, and neuroleptics.[61] These classes of medications may facilitate the secretion of ADH or increase renal responsiveness to ADH.[61]

A substantial decline in cognitive function has been reported in studies of patients with some malignancies, particularly breast cancer.[1] It has been hypothesized that two distinct pathways are involved: psychological and social factors associated with the diagnosis of cancer and a physiologic effect of cancer treatment, particularly with medications that cross the blood–brain barrier. These effects include decreased functional connectivity, dysregulation of proinflammatory cytokine concentrations, and direct cytotoxic effects to the visual system.[48,49,72]

Nonsteroidal anti-inflammatory drugs are believed to cause aseptic meningitis through hypersensitivity responses.[30] Only a small number of nonsteroidal anti-inflammatory drugs (diclofenac, ibuprofen, ketoprofen, naproxen, sulindac, and tolmetin) have been associated with aseptic meningitis, which may be attributable to degree of lipophilicity and penetration of the blood–brain barrier.[31] Reye syndrome has been associated with aspirin use in children less than 18 years of age.[30] The mechanism is thought to be inhibition of lipid beta-oxidation and mitochondrial disarrangement, leading to urea genesis and ketogenesis and ultimately hyperammonemia, hypoglycemia, elevated serum lactate, free fatty acids and dicarboxylic acid release.[30] The cyclooxygenase-2 inhibitors rofecoxib and valdecoxib have been associated with increased incidences of stroke and myocardial infarction by inhibiting prostacyclin, producing a prothrombotic state.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The clinical presentation of patients with drug-induced cognitive disorders is diverse and may involve acute or chronic changes in states of wakefulness, attention, or memory.[73] Anticholinergic drugs have been associated with memory impairment, confusion, hallucinations, sedation, and dysphoria.[18] The most common cognitive effects associated with anticonvulsants are psychomotor slowing, reduced vigilance, and impairment in memory and mood.[35] In contrast, many patients receiving corticosteroids exhibit mood elevation, and some may experience euphoria, insomnia, restlessness, and increased motor activity.[74] Others become anxious, depressed, or present with psychotic symptoms. Common central nervous system adverse signs and symptoms caused by medications are listed in **Table 17-3**.[1,7,18,25,27,28,35,50,69,74-76]

Table 17-3 Signs and Symptoms Associated with Drug-Induced Cognitive Disorders[1,7,18,25,27,28,35,50,69,74-76]

- Sedation/drowsiness
- Insomnia
- Decreased attention
- Impaired concentration
- Memory disorders
- Confusion
- Myoclonus
- Hallucinations
- Delirium
- Seizure disorders

- Impaired performance on assessment instruments (e.g., Wechsler Adult Intelligence Scale, Digit Span/Digit Symbol, CogHealth, Hopkins Verbal Learning Test) to assess executive function, attention, concentration, intelligence, memory and recall, psychomotor ability, processing verbal ability, vigilance, and visuospatial and visuomotor ability
- Seizure activity on electroencephalogram
- Magnetic resonance imaging changes (e.g., cerebral atrophy, diffuse white matter hyperintensities, ventricular enlargement, cortical calcifications)

Central nervous system effects of benzodiazepines include sedation, hypnosis, decreased anxiety, muscle relaxation, anterograde amnesia, and anticonvulsant activity.[75] As the dose is increased, sedation progresses to hypnosis and then stupor. There have been reports of delirium in hospitalized patients receiving benzodiazepines, more often associated with long-acting agents and higher doses of all benzodiazepines.[7] Long-term use of benzodiazepines in the elderly has been associated with a higher risk for cognitive decline than with episodic, recurrent, or no use of benzodiazepines.[19] Benzodiazepines may also cause paradoxical effects or disinhibition reactions.[75] Euphoria, hallucinations, sleep-walking, sleep-talking, hypomanic behavior, hostility, and rage have been reported with use of various benzodiazepines. These reactions are rare and may be dose-related.

Cases of reversible pseudoatrophy of the brain and mental deterioration have been reported in association with valproate in children.[67] In these reports, the serum valproate concentration was near or above 100 mg/L, magnetic resonance imaging documented pseudoatrophy, and there was a loss of 18–26 intelligence quotient (IQ) points as tested on the Wechsler Intelligence Scale for Children III. The scores with this test are normative IQs with a mean of 100 and a standard deviation of 15.[77] Some of these reports also mentioned the simultaneous presence of other adverse effects of valproate, such as tremor, weight gain, alopecia, ataxia, and nystagmus.[76]

Differentiating between cognitive dysfunction that is drug-induced with that due to a nondrug-induced disease process can be complex. This is especially true in patients with disorders such as epilepsy, Parkinson disease, and human immunodeficiency virus (HIV).[18,78,79] The “five foes” of mental competence in patients with epilepsy have been described as heredity, brain damage, seizures, anticonvulsant medications, and psychosocial issues.[78] Some studies found earlier seizure onset, higher lifetime number of seizures, and having multiple seizure types contributed to lower IQ scores in pediatric patients with epilepsy. Neuropsychiatric problems of Parkinson disease, such as hallucinations, memory loss, confusion, and major neurocognitive disorder can be aggravated by antiparkinson medications.[18] Cognitive and motor impairment occurs in 20% of patients with advanced HIV.[79] Robertson and colleagues conducted a prospective study of HIV-positive patients enrolled in randomized antiretroviral trials and found that a history of immunosuppression (nadir CD4 cell count <200 cells/mm^3) was associated with an increase in neurocognitive impairment.[79] Of 458 patients who were classified as having mild impairment at baseline, 389 had a minimum of one follow-up visit with 172 (44%) improving while receiving highly active antiretroviral therapy.

The differential diagnosis of a patient with altered mental status can be extensive.[7,76,80] Because patients may not be able to provide an accurate history, interviews of family members or care providers may be essential to determine the patient's baseline mental status.[9] It is important to determine the timeline of development of the cognitive dysfunction, which may be described as either acute or insidious. The rate of drug absorption and penetration into the brain determines the speed of onset of acutely occurring drug-induced events.[53] A careful history of current prescription and nonprescription medication use, as well as the use of herbal supplements or other remedies is essential and should include information regarding any recent alterations in drug, dose, or adherence.[7]

The most common causes of cognitive disorders are mild and major neurocognitive disorders due to Alzheimer disease, vascular disorders, Parkinson disease, and substance/medication intoxication.[80] Other degenerative disorders that cause dementia include dementia with Lewy bodies, frontotemporal dementia, and multiple sclerosis.[80] Major neurocognitive disorders associated with chronic alcoholism may be linked to the associated malnutrition and deficiency of the B vitamins or to withdrawal syndromes. Thiamine (vitamin B_1) deficiency can lead to Wernicke encephalopathy, which in turn can progress to irreversible Korsakoff psychosis and death. Vitamin B_{12} deficiency, in addition to damaging peripheral nerves and causing sensory loss, can damage cerebral myelinated fibers, thereby inducing dementia. Another insidious cause of memory loss is chronic metal intoxication, such as that associated with lead, mercury, and aluminum poisoning.

Acute and chronic infections can also impair cognition.[80] Chronic diseases such as tuberculosis, cryptococcosis, advanced stages of HIV infection, and neurosyphilis must be considered. Prion illnesses such as Creutzfeldt–Jakob disease and bovine spongiform encephalopathy are rare. Elderly patients may experience delirium in association with acute infections such as urinary tract infections and pneumonia.[76]

Acute changes in mental status can serve as an alert for an underlying life-threatening medical problem.[73] Metabolic and endocrine disorders, including dehydration, hyperammonemia, hypercalcemia, hyponatremia, hypothyroidism, kidney disease, liver failure, and hypoxemia should be considered in the differential diagnosis.[80-82] Withdrawal from certain agents, including alcohol, barbiturates, benzodiazepines, and tricyclic antidepressants can also cause cognitive disturbances.[53,73]

Psychiatric diseases must also be considered in the differential diagnosis. Some patients with severe depression express confusion and inability to perform routine tasks.[80] Patients with schizophrenia or with a conversion disorder (mental disorders presenting as physical illnesses but lacking a physiologic basis) may experience cognitive dysfunction. In patients with conversion disorders, psychometric testing does not confirm memory loss. Schizophrenia is usually associated with delusions and hallucinations and initially with an intact memory, but unexplained progressive dementia develops in some patients late in life.

Table 17-4 provides a list of conditions to consider in the differential diagnosis of drug-induced cognitive disorders.[73,80,81] Diagnostic tests that can be performed to confirm or assist in the diagnosis are listed in **Table 17-5**.[75,76,80-82]

Table 17-4 Conditions to Consider in the Differential Diagnosis of Cognitive Disorders[73,80,81]

Neoplastic disease

- Primary brain tumor
- Metastatic brain tumor

Central nervous system disorders

- Extradural hemorrhage
- Chronic subdural hematoma
- Vascular dementia
- Postanoxia
- Normal-pressure hydrocephalus
- Stroke

Metabolic disorders

- Dehydration
- Hyperammonemia
- Hypercalcemia
- Hyperglycemia/hypoglycemia
- Hypoadrenalism
- Hyponatremia
- Hypothyroidism/hyperthyroidism
- Kidney disease
- Liver failure
- Hypoxemia

Infections

- Central nervous system infection (meningitis, encephalitis, brain abscess)
- Human immunodeficiency virus
- Neurosyphilis
- Prion diseases (Creutzfeldt–Jakob disease)
- Acute infection/sepsis

Vitamin deficiencies

- Thiamine (B_1) (Wernicke encephalopathy)
- B_{12} (pernicious anemia)
- Nicotinic acid (pellagra)

Toxic disorders

- Intoxication with drugs of abuse/alcohol and/or prescription medications
- Heavy metal intoxication
- Dialysis dementia (aluminum)
- Organic toxins

Psychiatric disorders

- Conversion disorder
- Depression
- Schizophrenia

Recurrent nonconvulsive seizures Degenerative disorders

- Alzheimer disease
- Dementia with Lewy bodies
- Frontotemporal dementia
- Parkinson disease
- Multiple sclerosis

Table 17-5 Tests for Evaluation of Patients with Cognitive Dysfunction[75,76,80-82]

- Thyroid function
- Vitamin B_{12}
- Complete blood count
- Electrolytes
- Computed tomography/magnetic resonance imaging
- Venereal Disease Research Laboratory (VDRL)
- Human immunodeficiency virus
- Chest x-ray
- Lumbar puncture
- Kidney function
- Liver function
- Serum ammonia concentration
- Urine toxin screen
- Urine heavy metals
- Psychometric testing
- Electroencephalogram

RISK FACTORS

Certain predisposing or precipitating factors may increase the risk of drug-induced cognitive dysfunction (**Table 17-6**).[7,34,63,73,81,83,84] Predisposing characteristics include age, cerebral damage, chronic illness, functional impairment, genetics, polypharmacy, and underlying cognitive impairment.[7,34,81] Precipitating factors include acute illness, infection, metabolic disturbances, dehydration, acute urinary retention, malnutrition, environmental and psychosocial factors, surgery, drug interactions, and dose–response relationships.[7,34,64,73,83,84] Confounding factors, such as those experienced with cancer treatment, may include dose intensity, duration of treatment, concomitant medications, radiation therapy, and other chemotherapy toxicities, including anemia, vascular injury and neurotoxicity.[1]

Table 17-6 Risk Factors for Drug-Induced Cognitive Disorders[7,34,63,73,81,83,84]

Predisposing characteristics

- Elderly
- Children
- Genetic predisposition
- Underlying cognitive impairment
- Chronic illness (e.g., alcoholism, HIV)
- Cerebral damage
- Functional impairment
- Polypharmacy

Precipitating factors

- Acute illness
- Acute infections/sepsis (brain abscess, encephalitis, meningitis, pneumonia, urinary tract infection)
- Metabolic disturbances (hyperammonemia, hypercalcemia, hyperglycemia or hypoglycemia, hyponatremia, hypothyroidism)
- Hypoxemia
- Dehydration
- Acute urinary retention
- Malnutrition
- Environmental (heavy metal intoxication, organic toxins, aluminum toxicity associated with dialysis)
- Psychosocial factors (drug abuse, depression)
- Surgery
- Drug interactions leading to elevated serum concentrations of causative agents and/or additive pharmacodynamic effects
- Elevated serum concentrations of causative agents

HIV = human immunodeficiency virus.

In one study, altered mental status was present in 40% of patients older than 70 years of age who presented to the emergency department.[73] There are a number of pharmacokinetic changes in the elderly that place them at higher risk of cognitive dysfunction. In elderly patients there is a lesser degree of gastric acid secretion, reduced gastrointestinal blood flow, and a diminished rate of gastric emptying, translating to reduced ionization and solubility of certain drugs and a delay in drug absorption.[85] As a person ages, there is a decrease in lean body mass and an increase in body fat. These changes affect the distribution and volume of distribution of lipophilic and hydrophilic drugs. Binding to serum albumin and α_1-acid glycoprotein is a determinant of drug distribution and the fraction of drug available for activity. Albumin primarily binds with acidic and some basic drugs; albumin concentrations decrease with increasing age. Conversely, α_1-acid glycoprotein binds to basic and neutral drugs; there is either no change or an increase in the α_1-acid glycoprotein concentration with advancing age. In addition, serum drug concentrations may be increased in patients with infection, trauma, myocardial infarction, and chronic disease. Hepatic metabolic activity—especially phase 1 reactions, including oxidation, reduction, and hydrolysis—is diminished in the elderly.[86] Benzodiazepines that are only metabolized by conjugation (lorazepam, oxazepam, and temazepam) are preferred in the elderly to benzodiazepines that also undergo phase 1 reactions to prevent accumulation.[8] Glomerular filtration rate, creatinine clearance, and tubular secretion and absorption all decline in elderly patients. Older patients may also be more sensitive to the effects of some medications because of pharmacodynamic changes.[7,85,86] There may be reduced cholinergic transmission and decreases in receptor numbers and sensitivity.[7,86] Exposure to at least three possible anticholinergic agents for a minimum of 90 days in adults ≥65 years of age was associated with an odds ratio (OR) for a diagnosis of mild cognitive impairment of 2.73 (95% CI 1.27–5.87) compared to those having no anticholinergic exposure.[87] Older age, smoking and excessive perspiration are risk factors for cognitive dysfunction associated with the syndrome of drug-induced inappropriate antidiuretic hormone secretion.[61]

Younger age has also been implicated as a risk factor for specific drug-induced alterations of cognitive function. In a 16-week double-blind, placebo-controlled, randomized add-on study in 86 children with partial seizures, topiramate was associated with difficulty with attention and concentration (12% versus 2%) and forgetfulness and impaired memory (7% versus 0%).[88] Phenobarbital has been shown to slow cognitive processing speed compared with carbamazepine and valproate in children.[10,34] Detriments to attention and memory caused by anticonvulsant medications may impact long-term neurodevelopment in children.[35] Phenobarbital use in 217 children 8–36 months of age resulted in an IQ that was 8.4 points lower on the Standfort-Binet Intelligence Scale, Form L-M compared to that in controls (95% CI –13.3 to –3.5, $p = 0.0057$) after 2 years of treatment.[89] Six months later after a taper and discontinuation, the IQ was lower by 5.2 points in the phenobarbital group (95% CI –10.5 to –0.04, $p = 0.052$).[89] Children ($n = 139$)

were retested after completing at least first grade and after 86% had discontinued therapy for 3 or more years.[90] There was no significant difference in IQ points at that time for the phenobarbital group (102.2 versus 105.7 for placebo, $p = 0.09$) but a significantly lower score on the Wide Range Achievement Test reading achievement standard score (87.6 versus 95.6, $p = 0.007$).

Genetic polymorphisms (deoxyribonucleic acid sequence variation) are responsible for inherited differences in drug metabolism and disposition and the resulting effects.[91] In addition, polymorphism in genes encoding drug transporters and targets cause modifications in drug response. Genetic variability affects sensitivity to opioid analgesia and may determine a predisposition to adverse effects.[81] In studies of the addition of topiramate or valproate to carbamazepine therapy, a subgroup of patients who are particularly sensitive to the adverse cognitive effects of topiramate was identified.[92,93] Galimberti and colleagues identified a mutation in the *MT-ATP8* (mitochondrially-encoded adenosine triphosphate synthase 8) gene of a child who developed reversible mental deterioration with brain pseudoatrophy while undergoing valproate therapy.[94] In patients who received androgen-deprivation therapy for prostate cancer, there were 15 single nucleotide polymorphisms (SNPs) associated with impaired cognitive performance (from a total of 384 SNPs) as measured with the International Cognition and Cancer Task Force recommended criteria.[4] Patients with the wild type (GG) of one variant (rs1047726 in G protein subunit B3, GNB3) had higher odds of impaired cognitive performance at 12 months compared to those with one or more A alleles (OR 14, 95% CI 2.97–66.09).[4] Womack and Heilman described the case of a 46-year-old woman in whom memory loss and abnormal memory test results developed, but improved upon discontinuation of tolterodine therapy.[63] The authors suggested that she might be one of the 7% of the population lacking the cytochrome P-450 2D6 enzyme responsible for converting tolterodine to the active 5-hydroxymethyl metabolite. In poor metabolizers, the more lipophilic parent compound predominates and crosses the blood–brain barrier more easily than the metabolite, which is more hydrophilic. Cattie and colleagues found patients with hepatitis C virus genotype 1 had significantly greater neurocognitive decline than patients with other genotypes when treated with pegylated interferon and ribavirin.[24]

Cognitive adverse effects of many medications occur more commonly in association with higher serum concentrations and with polypharmacy.[35,84] Therapeutic serum concentration ranges have been identified for many narrow therapeutic index medications, including phenytoin (10–20 mg/L), carbamazepine (4–12 mg/L), phenobarbital (10–40 mg/L), valproic acid (50–100 mg/L), lithium (0.5–1.2 mEq/L), digoxin (0.5–2 ng/mL), theophylline (5–15 mg/L), lidocaine (1–5 mg/L), and combined amitriptyline + nortriptyline (120–250 ng/mL).[84] Many patients experience cognitive adverse events when the upper limit of the therapeutic range is exceeded. Doses must be individualized for efficacy and to prevent toxicity. Some patients may not tolerate the medication at a lower serum concentration, while others may tolerate much higher concentrations. Additive effects are often observed when sedative or hypnotic medications are taken concurrently.[75] Tolerance may develop to some effects of medications, but other effects may linger. With benzodiazepines, patients report subjectively that drowsiness subsides after a few days, but tolerance to the impairment of some measures of psychomotor performance, such as visual tracking, does not occur.

Adverse central nervous system reactions have been attributed to histamine-2-receptor blockers.[20,57,95] Slugg and colleagues determined that ranitidine-induced adverse central nervous system reactions are more likely to occur in patients with estimated creatinine clearances <50 mL/min than in those with estimated creatinine clearances >50 mL/min.[95] Patients with creatinine clearances <50 mL/min had higher peak plasma concentrations, higher average plasma concentrations, and larger areas under the plasma concentration: time curve than patients who did not have kidney disease.

Postoperative confusion occurs commonly, with a reported incidence between 5% and 45% in the elderly.[96] Common causes include opioids, benzodiazepines, and anticholinergics.[34,96] Short-term and long-term postoperative cognitive dysfunction has been evaluated in both elderly and middle-aged patients.[97,98] Postoperative cognitive dysfunction was present in 25.8% and 9.9% of 1,218 patients ≥60 years of age at 1 week and 3 months after surgery, respectively, as compared with 3.4% and 2.8% in nonsurgical control subjects from the United Kingdom ($p < 0.0001$ and $p = 0.0037$).[97] Risk factors were increasing age, duration of anesthesia, minimal education, a second procedure, postoperative infections, and respiratory complications. In a study investigating patients 40–60 years of age who underwent surgery, cognitive dysfunction was reported in 19.2% at 1 week postoperatively, as compared with 4% of nonsurgical control subjects ($p < 0.001$).[98] The major risk factors for cognitive dysfunction at 7 days were supplementary epidural analgesia and reported avoidance of alcohol consumption.

MORBIDITY AND MORTALITY

There are few published data regarding the influence of drug-induced cognitive impairment on morbidity or mortality. However, one prospective study of hospitalized elderly patients demonstrated that the presence of delirium prolonged the duration of hospitalization from 7.2 days to 12.1 days, and increased the mortality rate from 1% to 8%.[36]

PREVENTION

A number of strategies have reduced the likelihood of occurrence of drug-induced cognitive disorders including adjusting drug doses in patients with liver or kidney disease, limiting the total dose of medications with known dose–toxicity relationships, monitoring plasma concentrations, slowly titrating the dose, using alternative agents with a lower risk of inducing cognitive dysfunction, limiting the total number of medications, and using consensus criteria. **Table 17-7** provides a summary of measures that can be taken to reduce the risk of drug-induced cognitive disorders.[35,38,76,99-102]

Table 17-7 Approaches to Help Prevent Drug-Induced Cognitive Disorders[35,38,76,99-102]

- Adjust dose for patients with kidney and/or liver disease where applicable
- Limit total dose where possible
- Limit total number of medications
- Use adjunctive medications
- Use around-the-clock regimen
- Perform routine plasma concentration monitoring of medications with defined ranges for efficacy and toxicity
- Upon initiation of medications, use a slow titration to target range
- Use alternative medications with less association for cognitive adverse events
- Use consensus guidelines for safe medication use in specific populations

Adjusting drug doses and/or dosing intervals in patients with liver or kidney disease is not only important when initiating therapy, but it is also critical in patients with severe illness in which organ function may decline suddenly and precipitously. Histamine-2-receptor blockers are an example of a class of medications for which careful dose adjustment is necessary.[95] Other medications should be avoided altogether in patients with liver or kidney disease. Meperidine, for example, has a neurotoxic active metabolite, normeperidine, that accumulates after repeated doses in patients with kidney disease.[99]

Another risk reduction strategy is to limit the total dose of a potentially offending agent for which a known dose–toxicity relationship exists.[81] In patients requiring pain management with opioids, for example, the addition of a nonopioid coanalgesic or an adjuvant analgesic and around-the-clock administration can decrease the total required opioid dose.[81,99] Proper management of pain is important, as was demonstrated in a study of postoperative patients 50–80 years of age, which found that pain, not analgesic intake, predicted a decline in mental status during the first 5 days after surgery.[100] Other pain management approaches to consider include the use of a therapy targeting the cause of pain (antitumor therapies such as radiotherapy, chemotherapy, and surgery) or use of a regional anesthetic or neuroablative intervention.[81]

Medications such as anticonvulsants and lithium require routine plasma concentration monitoring to maintain concentrations within specified ranges.[84] Even though plasma topiramate concentrations are not tested routinely, in a study of correlates of topiramate-induced cognitive impairment, the largest causal relationship was plasma concentrations, which varied by 55-fold among 158 healthy volunteers.[103] The authors performed a genome-wide association study (GWAS), including a focused analysis near genes considered candidates for influencing topiramate cognitive response. No significant association was found among the healthy volunteers or with a comparison of a GWAS of cognitive adverse effects in patients with epilepsy taking topiramate. For some medications, minor adverse effects often appear as the plasma concentrations rise before major cognitive toxicities are experienced.[84] To an astute clinician, these minor adverse effects serve as a warning that more serious cognitive impairment may be imminent. For example, gastrointestinal distress may be an early symptom of valproic acid toxicity, while fatigue may be an early indicator of impending toxicity associated with phenytoin or topiramate. Patients become tolerant to some of the adverse cognitive effects of some medications when doses are slowly titrated upward. This is the case with topiramate, for which therapy should be initiated at a low dose and titrated to the target dose over a period of 1–2 months.[92]

Another strategy for the prevention of cognitive disturbances involves the use of medications with lower risk. In a single site retrospective study of 2860 adult outpatients with epilepsy, topiramate (18.5%, 95% CI 1.78–7.49%) and phenytoin (11%, 95% CI 1.08–3.77%) were most likely to be associated with intolerable cognitive adverse effects.[104] Gabapentin, pregabalin, and carbamazepine were the least likely of the antiepileptic medications to cause these adverse effects. Residual daytime sedation has been associated with the use of benzodiazepines and the benzodiazepine-receptor agonist zoldipem.[35,101]

The potential for drug interactions and additive pharmacodynamic effects should be considered as new medications are added to a patient's treatment regimen. The odds for experiencing adverse drug reactions, adjusted for age and duration of symptoms, were shown to increase as the number of drugs used increased in an elderly population.[38] Compared to patients taking zero or one prescription medication, the odds ratio for adverse drug reactions was 2.7 (95% CI 0.9–7.8) in those taking two or three medications, 9.3 (95% CI 3.3–26.6) for those taking four or five medications and 13.7 (95% CI 3.6–51.9) for those taking six or more medications.[38] In a prospective study of 72 children with epilepsy, in which siblings of 45 of the children served as controls, investigators reported that 11% of children with a persistent decrease in IQ score had a significantly higher incidence of toxic plasma drug concentrations, took a larger number of medications simultaneously, had seizures that were more difficult to control, had a higher total number of seizures, and began to have seizures at a younger age.[78]

A tool used to minimize impact of polypharmacy is the Anticholinergic Cognitive Burden (ACB) list, which scores the anticholinergic activity of medications as mild (ACB score 1) or severe (ABC score 2 or 3).[87] Drugs with mild anticholinergic effects have serum anticholinergic activity or in vitro affinity to muscarinic receptors but no known clinically relevant negative cognitive effects. Drugs assigned higher scores have established and clinically relevant cognitive anticholinergic effects.

Federal regulations have been enacted to protect the elderly, a population that is at increased risk for the development of adverse events due to medications. The Omnibus Budget Reconciliation Act of 1987 contained the Federal Nursing Home Reform Bill, which gave the right of long-term care residents to be free from unnecessary physical and chemical restraints.[105] Reportable quality measures, such as the Minimum Data Set for nursing home residents, improve quality for residents by providing regular organized assessments of each resident's physical and mental status.[106] The Beers criteria, first published in 1997 and updated in 2003 and 2012, provide a consensus statement of medications that are potentially inappropriate in older adults in general and in older adults with common medical conditions.[102,107,108] The Beers criteria were accepted by the Centers for Medicare and Medicaid Services for nursing home regulation in 1999.[107] The 2012 update used a comprehensive and systematic review to divide 53 medications or classes of medications into three categories: (1) potentially inappropriate medications and classes to avoid in older adults, (2) potentially inappropriate medications and classes to avoid in older adults with certain diseases and syndromes that the listed drugs can exacerbate, and (3) medications to be used with caution in older adults.[108]

Prognostic molecular testing, as in the case of patients with breast cancer, can assist with identifying patients that might not benefit from prolonged cancer chemotherapy or those at low risk for recurrence, thus preventing overtreatment and limiting adverse events for those populations.[109]

MANAGEMENT

A summary of management strategies for drug induced cognitive disorders is provided in **Table 17-8**.[20,25,81,110,111] Treatment of drug-induced cognitive disorders may include discontinuation of the offending agent with or without adjuvant medications, dose reduction, substitution of a sustained-release formulation, symptomatic management, cognitive rehabilitation, and/or complementary therapies. In some instances, such as in patients with epilepsy or bipolar disease, it may be necessary to initiate treatment with another medication before therapy with the offending agent can be discontinued.[25,35] Use of a sustained-release formulation that may ameliorate toxicity associated with peak plasma concentrations has been recommended for patients with lithium-induced cognitive impairment.[25]

Table 17-8 Management of Drug-Induced Cognitive Disorders[20,25,81,110,111]

- Distinguish between medication effects and symptoms caused by comorbid conditions
- Discontinue the offending agent and use alternative medications
- Reduce the dose of the offending agent
- Where available, use a sustained-release formulation to prevent peak serum concentrations associated with adverse events
- Provide symptomatic treatment
- Treat comorbidities
- Provide cognitive rehabilitation and training
- Complementary therapies
- Provide supportive measures

Discontinuation of some medications such as benzodiazepines and SSRIs may cause a withdrawal reaction.[110,112] Withdrawal symptoms peak from 24 to 72 hours after discontinuation of short- to intermediate-acting agents.[113] These reactions occur more often in patients receiving higher daily doses, with agents having shorter half-lives, those undergoing a longer duration of daily drug therapy, and in association with more rapid rates of tapering.[110] Other predictors of poor outcome following discontinuation of benzodiazepines include a diagnosis of panic disorder, higher levels of anxiety or depression before tapering, higher levels of personality psychopathology (e.g., neuroticism, dependency), and concomitant alcohol and/or substance dependence or abuse. Tapering of therapy has been recommended for patients receiving daily diazepam doses of >10 mg or its equivalent (2 mg lorazepam, 1 mg alprazolam) after patients' anxiety or panic symptoms have been reduced. One recommended schedule is to taper by 25% per week until 1–2 mg equivalents of alprazolam is achieved, then decrease by 25% of the remaining dose every week.[113] Therapy with carbamazepine 200–800 mg/day, imipramine 25 mg/day, valproate 500–2,500 mg/day, and trazodone 100–500 mg/day has been shown to improve benzodiazepine tapering success rates, but has not been shown to diminish withdrawal severity.[114-116] The Physician Withdrawal Checklist (PWC-20) for benzodiazepines and the Discontinuation Emergent Signs and Symptoms (DESS) checklist for SSRIs are helpful tools to differentiate between discontinuation symptoms of rebound/withdrawal and return of anxiety/depression.[112,117] Psychostimulant agents antagonize opioid-induced sedation and cognitive impairment in postsurgical patients and in those with chronic cancer.[81] However, these agents can also cause cognitive adverse effects, including hallucinations, delirium, and psychosis, as well as noncognitive adverse events such as decreased appetite and tachycardia. A short-acting benzodiazepine such as lorazepam is often administered for severe agitation, and antipsychotic drugs such as haloperidol are often administered for the treatment of patients with delirium. Several studies have shown that opioid rotation, also referred to as opioid switching or opioid substitution, can minimize delirium or agitated confusion. Dose conversion tables should be used cautiously as guidelines. Because of incomplete cross-tolerance to opioids in tolerant patients, it has been recommended to decrease the dose of the new opioid by 30–50%. Cherny and colleagues published detailed instructions regarding the manner in which to perform opioid rotation.[81] Liothyronine 25–50 mcg daily was found to improve cognitive functioning in patients receiving lithium, even in the absence of hypothyroidism.[25]

The pharmacokinetic properties of a medication most often determine the duration of adverse cognitive effects.[53] The duration may be affected by redistribution from the brain into other tissues, as occurs with highly lipid-soluble drugs such as diazepam. With other central nervous system depressants, drug metabolism and elimination determine the duration of effect of the parent drug and any active or toxic metabolites. These factors may be influenced by age, disease, genetics, and concomitant medications.

It is important to also screen and treat possible underlying causes of cognitive dysfunction such as metabolic disturbances and infections as well as comorbidities such as anxiety, depression, fatigue and insomnia, which may be associated with drug-induced cognitive dysfunction such as that associated with cancer chemotherapy.[73,111]

Nonpharmacologic interventions have also been shown to be of benefit. Cognitive rehabilitation approaches may significantly improve patient functioning.[118] One approach is for caregivers and family members to orient confused patients to person, place, and time.[99] Supportive measures include convenient arrangement of the home or work environment, use of notes, and avoidance of distractions.[14] Cognitive training (memory and speed process training) and physical activity interventions (bicycling with speed feedback and modified hatha yoga) improved cognitive function in patients with breast cancer.[119] Other complementary/integrative medicine therapies include acupuncture, hypnosis, massage therapy, meditation, relaxation and biofeedback.[111]

INFORMATION FOR PATIENTS

Patients and/or their caregivers should be informed that the prescribed medication has been known to cause cognitive dysfunction, and they should be informed of associated signs and symptoms. Patients should be warned regarding the potential hazards of driving or using machinery and should be aware that alcohol could have additive effects when used concurrently. Patients and their caregivers should be instructed that healthcare providers should be contacted if the prescribed therapy causes intolerable cognitive effects so that appropriate changes in therapy can be implemented.

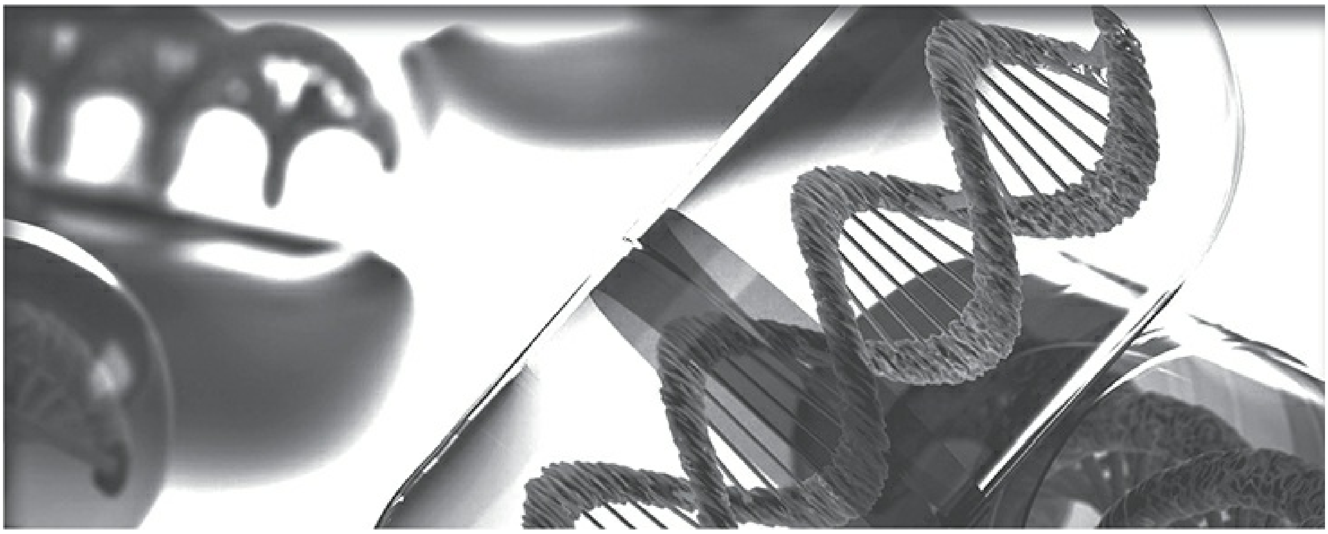
DRUG-INDUCED PSYCHIATRIC DISEASES

CHAPTER 18 Depression

CHAPTER 19 Anxiety

CHAPTER 20 Psychosis



CHAPTER 18

Depression

Sheila Botts and Melody Ryan

Depression is one of the most common psychiatric illnesses. Depression may interfere significantly with a patient's daily functioning and quality of life. Untreated depression is associated with substantial morbidity and increases the risk of suicide and death. The lifetime risk of suicide among patients with depression is 2.2–15%.[1,2] Depression is a biologic illness with an unknown cause. Drug-induced depression is similar in presentation to idiopathic depression and carries similar risks of morbidity and mortality. Although the overall prevalence is unknown, drug-induced depression poses a significant challenge for practitioners, as it may undermine the effectiveness of much-needed treatment. Treatment-emergent suicidality (e.g., suicidal ideation and behavior) has been characterized independently, even though it often occurs with mood changes and poses significant risks to the patient.

CAUSATIVE AGENTS

Depression has been associated with many drugs, including anti-infectives, cardiovascular agents, central nervous system (CNS) drugs, dermatologic agents, hormonal treatments, and immunologic and cancer chemotherapy drugs. The

Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (*DSM-5*), defines *medication-induced depression* as a "prominent and persistent disturbance of mood that occurs during use of a medication causally related to depression, or within 1 month of intoxication or withdrawal of therapy with a medication."[1] Symptoms must be severe enough to result in clinically significant distress in social, occupational, or other areas of functioning. The clinical features of medication-induced depression may be similar to those of a major depressive disorder (MDD) but do not have to meet full diagnostic criteria. In the evaluative literature, depression may be characterized as a specific symptom (i.e., depressed mood), a cluster of depressive symptoms, or as a diagnostic entity (e.g., MDD) although the latter is less common. For the purposes of this chapter, depression is defined as the presence of any one of these three characterizations and which is severe enough to cause a disruption in daily function. Suicide and suicidality are often associated with depression. Suicidality associated with antidepressants, antipsychotics, and anticonvulsants is defined as suicidal thoughts or behaviors or suicide.

Table 18-1 Agents Implicated in Drug-Induced Depression

Drug	Reported Incidence[a]	Level of Evidence[b]
ANTI-INFECTIVE AGENTS[3-15]		
Cycloserine	NK	C
Ethionamide	NK	C
Fluoroquinolones	NK	C
Mefloquine	NK	C
ANTIVIRAL AGENTS[16-22]		
Efavirenz[29]	1.6–2%	A
CARDIOVASCULAR DRUGS[23-36]		
β-blockers	NK	C
Clonidine	1.5%	C
Digitalis	NK	B
Guanethidine	1.5%	C
Methyldopa	3.6%	B
Reserpine	7%	B
CENTRAL NERVOUS SYSTEM AGENTS[36-89]		
Anticonvulsants[36-73]		
Levetiracetam	4%	A
Phenobarbital	40%	B

Primidone	70%	B
Phenytoin	NK	C
Tiagabine	3%	A
Topiramate	5–10%	A
Vigabatrin	12.1%	A
ANTIDEPRESSANTS[74,c]		
SSRIs, SNRIs, TCAs	1–4%	A
Aripiprazole	NK	C
Quetiapine	NK	C
Lurasidone	NK	C
ANTIMIGRAINE[75]		
Triptans	23%	B
MISCELLANEOUS[76-89]		
Sodium oxybate	10%	B
Tetrabenazine	15%	B
Varenicline	1–3%	A[d]
HORMONAL AGENTS[90-114]		
Corticosteroids	1.3–18%	B
Oral contraceptives	NK	B
GnRH agonists	26–54%	B
Tamoxifen	1–20%	A[d]
Aromatase inhibitors	5–13%	A
Finasteride	NK	B
IMMUNOLOGIC AND CANCER CHEMOTHERAPY AGENTS[115-146]		
INFα	13–33%	A
INFβ	0–33%	A
Interleukin-2	NK	C
TNFα inhibitors	NK	C
Vincristine	NK	C
RETINOIC ACID DERIVATIVES[145-165]		
Isotretinion[3-21]	1–5.5%	B

GnRH = gonadotropin-releasing hormone, INF = interferon, NK = not known; SNRI = serotonin-norepinephrine reuptake inhibitor, SSRI = selective serotonin reuptake inhibitor, TCA = tricyclic antidepressant; TNF = tumor necrosis factor.

[a] Incidence reported in the treated population.

[b] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[c]Refers to risk of suicidal ideation when used as antidepressant.

[d]Randomized studies do not support an increased risk of depression.

All drugs associated with inducing depression for which evaluative support is available in the literature are reviewed in this chapter.[3-182] The literature supporting an association of drugs with depression is largely comprised of case reports, postmarketing surveillance, and retrospective observational studies, making the case for causality difficult. There are few prospective, controlled trials with objective assessments of depressive symptoms or diagnostic criteria. When available, these data are discussed for each agent. A list of drugs associated with depression and the estimated incidence for each are presented in **Table 18-1**.[3-165]

EPIDEMIOLOGY

The estimated lifetime prevalence of depression in the general population is approximately 17%.[183] Depression occurs at a much higher rate in patients with chronic illnesses such as diabetes and cardiovascular disease.[184] Although many drugs have been associated with depression, few have been adequately studied to identify the degree of risk that they impart above and beyond that normally present in the population of patients with disease.

ANTI-INFECTIVE AGENTS

Adverse psychiatric effects have been reported in association with most antibiotics, but are still considered relatively rare events.[3] Depression has been reported in patients taking fluoroquinolones, the antitubercular agents cycloserine and ethionamide, and the antimalarial agent mefloquine.[3-15] These data, however, are limited to case reports, and the overall prevalence is unknown.

ANTIVIRAL AGENTS

Both non-nucleoside reverse transcriptase inhibitors (NNRTIs) and protease inhibitors have been associated with depression. The NNRTI efavirenz appears to confer the greatest risk. In over 1,000 patients treated with efavirenz in clinical trials for an average of 1.6 years, severe depression was reported with an incidence of 1.6%, and suicidal ideation occurred in 0.6% of patients.[16] The risk of depression and suicidal ideation increased to 2% in patients with a history of psychiatric disorders. In contrast, several prospective trials have not shown an increased risk of depression associated with efavirenz treatment. A 48-week randomized, controlled trial of patients receiving a protease inhibitor–containing regimen or efavirenz-containing once-daily regimen failed to find a difference in the risk of depression during maintenance treatment.[17] An additional prospective trial compared neuropsychiatric effects of an efavirenz-containing antiviral regimen with those in patients on therapy that did not contain efavirenz.[18] The proportion of efavirenz-treated patients who reached the threshold Center for Epidemiologic Studies—Depression (CES-D) score for clinical depression declined over the course of the study from 34.1% at baseline to 22.3% at week 184. Finally, a large cohort study of patients newly diagnosed with human immunodeficiency virus (HIV) also did not find an increased incidence of depression in those taking efavirenz-containing regimens.[19] In summary, it is difficult to assess the true incidence of efavirenz-associated depression, because depression has been associated with other agents with which efavirenz is almost always prescribed in combination. Other NNRTIs (nevirapine, abacavir), and protease inhibitors (indinavir) have also been noted in clinical case reports to cause depression.[18-22]

CARDIOVASCULAR AGENTS

Antihypertensive agents, including angiotensin-converting enzyme inhibitors, β-blockers, calcium channel blockers, antiadrenergic agents (e.g., reserpine, methyldopa, guanethidine, and clonidine), and thiazide diuretics have been implicated in causing depression in case reports. With the exception of antiadrenergic agents, β-blockers and digoxin, little empirical evidence exists to support this association. Reserpine, methyldopa, and guanethidine increase patients' risk of depression, but these agents are no longer commonly used.[23-27] Case report data support the association between clonidine and depression. However, larger evaluative studies suggest that the incidence of depression in patients taking clonidine is similar to that in the general population.[28] The risk of depression associated with β-blocker therapy remains somewhat controversial. In addition to case reports, two epidemiologic studies support an association with depression, but this link was not confirmed in two prospective studies.[29-32] It has been suggested that depressive disorders rarely develop in patients treated with β-blockers, but that these patients experience typical β-blocker adverse effects, which leads to misdiagnosis of depression. Studies that have incorporated diagnostic criteria for depressive disorders have failed to identify an association between β-blockers and depression.[33,34] Digoxin has been associated with depression in case reports and two small prospective studies.[34-36] In a community sample, Palinkas reported that elderly women taking digoxin had higher rates of significant depressive symptoms than women not taking digoxin (10.5% versus 6.5%), although this difference was not statistically significant.[35] In a second study of 335 patients postmyocardial infarction, digoxin exposure was associated with an increased risk of depression at the 3- to 4-month follow-up visit.[36]

CENTRAL NERVOUS SYSTEM AGENTS

Several CNS-acting drugs have been associated with depression, including antiepileptic drugs (AEDs), benzodiazepines, physostigmine, and 5-hydroxytryptamine (5-HT)$_1$ agonists (triptans). Most AEDs have been reported to cause depression. Conversely, many AEDs may be used to stabilize patients with mood disorders. Sodium valproate, carbamazepine, and lamotrigine have U.S. Food and Drug Administration (FDA)-approved indications for bipolar disorder. In addition, several AEDs including phenytoin and carbamazepine have demonstrated effectiveness in the management of unipolar depression.[37,38] It is important to note that, because of ethical considerations, very few of the AED trials are placebo-controlled. Because of the various CNS activities of the AEDs used as comparators, it is difficult to judge the exact prevalence of depression caused by these agents. Also, the rate of depression in patients with epilepsy is very high (32–48%) and the lifetime prevalence of suicide and suicide attempts is 5–14% in this population.[39] Therefore, this increase in the incidence of mood disorders can be only partially attributed to the AEDs. All of the AEDs, particularly at higher doses, are associated with lethargy, fatigue, drowsiness, and asthenia, which may mimic depression. All AEDs have FDA-mandated warnings regarding suicidality.[40] This requirement stems from data from 199 placebo-controlled trials of 11 AEDs (carbamazepine, felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, valproate, zonisamide).[40] The investigators reported suicidal ideation or behavior in 0.43% of patients taking AEDs compared with 0.22% of those taking placebo. The relative risk of suicidal behavior or ideation in patients taking AEDs for epilepsy was 3.53 (95% CI 1.28–12.1), compared with 1.51 (95% CI 0.95–2.45) for those taking AEDs for psychiatric reasons and 1.87 (95% CI 0.81–4.76) for those taking AEDs for other reasons.[40] No specific AED appears to confer greater risk, and no demographic group appears to be at higher risk. In the wake of this study and subsequent warning, several other investigations have been conducted to attempt to provide clarity regarding the risks of suicidal ideation, behavior, and depression.

A large cohort study of 8,211 patients found no excess risk of suicidal ideation associated with AED use.[41] However, a nested case-controlled study of 44,300 patients ever given AEDs found increased odds (OR 3.08, 95% CI 1.22–7.77) of self-harm or suicidal behavior with a group of newer AEDs associated with depression (levetiracetam, vigabatrin, topiramate, tiagabine) compared with patients not currently taking AEDs.[42] The odds of suicidal behavior or self-harm were not higher in patients taking other AEDs, conventional agents, barbiturates, and newer AEDs with low association with depression compared to those in patients not currently prescribed AEDs. A retrospective database analysis of 2.15 million military veterans over the age of 65 years reported that taking AEDs was associated with an increased hazard of suicidal behavior (HR 4.10, 95% CI 3.85–

6.63).[43] Gabapentin, lamotrigine, levetiracetam, phenytoin, topiramate, and valproic acid were all significantly associated with suicidal behavior in this study. Another study of 449,269 veterans older than 65 years of age who were prescribed AEDs did not find an increased risk of suicidal behaviors associated with AED use; however, there was a trend toward an increase in suicidal behavior in patients who were taking levetiracetam or lamotrigine (OR 10.2, 95% CI 1.1–97).[44] A consensus statement of the World Psychiatric Association section of pharmacopsychiatry declined to identify suicidal behavior as a class effect.[45] An expert consensus statement from the International League Against Epilepsy stated that depression was associated with barbiturates, tiagabine, topiramate, vigabatrin, and zonisamide.[46] This panel further stated that withholding AED therapy to prevent depression and suicidality can also be harmful, even resulting in patient death.

Of the AEDs, the barbiturates are most strongly associated with depression in both adult and pediatric populations.[47,50] In one cross-sectional sample of adult patients in Mexico City, primidone use was strongly associated with depression, with an odds ratio of 4.089 (95% CI 2.094–7.985). In this sample, 70% of the patients treated with primidone were depressed.[50] In another study, phenobarbital was associated with an incidence of depression of 40%.[49] Data relating phenytoin use to depression are much less convincing. There are case reports of two patients with epilepsy with supratherapeutic serum phenytoin concentrations (22.7 mcg/mL and 25.5 mcg/mL) who had depressive symptoms. When the phenytoin dose was decreased or the medication was discontinued, the symptoms resolved.[51] A prospective study of 277 patients in whom tiagabine or placebo was added to baseline AED therapy found depression in 3% of those treated with tiagabine.[52] Topiramate treatment has been associated with new-onset depression in 5–10% of patients.[53] Pooled data analysis of perampanel trials found one case of suicidal ideation; 2.4% of patients taking 12 mg/day reporting depression, compared to 1.6% of patients given placebo (no statistical analysis performed).[54] Depression was reported in 4% of levetiracetam-treated patients compared to 2% treated with placebo.[55] Levetiracetam has been implicated as a cause of depression in a prospective study, a retrospective case series, and an additional case report.[56-58] In a prospective study of 71 treatment-refractory epilepsy patients administered levetiracetam, there was no mean change in the Beck's Depression Inventory (BDI) score from baseline to week 24.[59] However, five patients discontinued treatment due to psychiatric symptoms, of whom four had suicidal ideation. Vigabatrin-associated depression occurred in 12.1% of patients treated in double-blind, placebo-controlled clinical trials (p <0.001).[60] In a small, prospective study (n = 23) of patients with previous psychiatric diagnoses who were prescribed zonisamide, one patient developed major depressive disorder.[61] Pregabalin has also been associated with depression in case reports.[62,63] Two cases of depression activation in patients with bipolar disorder have been reported in association with rufinamide.[64]

Depression often is cited as an adverse effect of benzodiazepines, both during therapy and after discontinuation.[65] However, the literature supporting incident depression in patients taking benzodiazepines is not robust, and depression is reported infrequently in controlled clinical trials. Case reports and observational studies have identified an increased risk of depression in patients taking benzodiazepines.[66-69] These reports, however, do not control for confounding variables, such as history of depression, presence of comorbid depression, or concomitant medications, and are therefore difficult to interpret. One large cohort study of 8,211 patients found a relationship between benzodiazepine use and depressive symptoms and suicidality.[41] However, when results were adjusted for comorbid psychiatric conditions, including depression and anxiety, there was no association between benzodiazepine use and suicidal ideation. A prospective trajectory study conducted in 2,590 patients found increasing depression associated with baseline benzodiazepine use.[70] In an historical cohort of 58,967 people, an association between benzodiazepine use and severe anxiety, depression, and poor sleep outcomes was found.[71] In another study, the CES-D 10 was administered to 1,331 people age ≥65 years, of whom 288 (21.6%) had type 2 diabetes mellitus.[72] The investigators found an increased odds of depression in those using benzodiazepines or nonbenzodiazepine hypnotics compared to nonusers (OR 1.66, 95% CI 1.10–2.51). Depression and anxiety are highly comorbid syndromes, and the emergence of depression during benzodiazepine therapy may occur from a relapse or as a coincidental finding. Moreover, alprazolam administered in higher doses has been shown to have an antidepressant effect.[73]

Antidepressant medications are associated with an increased risk of suicidality in patients younger than 25 years of age.[74] Pooled analyses of 24 short-term placebo-controlled antidepressant trials in over 4,400 children and adolescents with MDD, obsessive–compulsive disorder, or other psychiatric disorders revealed that these drugs increase the risk of suicidality, although no suicides were reported. Antidepressant use in patients younger than 18 years of age resulted in an additional 14 cases of suicidality per 1,000 patients treated. A pooled analysis of 295 short-term placebo-controlled studies of antidepressants in over 77,000 adults aged 18–24 years with MDD or other psychiatric disorders showed an additional five cases of suicidality per 1,000 patients treated. There was no increased risk in adults aged 25–64 years, and there was a reduced risk in adults 65 years and older (six fewer cases per 1,000 patients). All antidepressant medications, including antipsychotics with an FDA indication for MDD or bipolar depression (e.g., aripiprazole and quetiapine, lurasidone), have a boxed warning for suicidality in the product information. Suicidality is an inherent risk in patients with major depression and should be considered when balancing the potential risks and benefits of antidepressant therapy in all age groups.

Only a single published epidemiologic study exists to implicate the antimigraine agents, triptans, as causative agents for depression. A cohort analysis of the West Midlands General Practice Research Database in the United Kingdom (UK) examined the incidence of depression in migraineurs receiving any oral triptan, sumatriptan, or the more lipophilic agents in this class (naratriptan or zolmitriptan).[75] A larger proportion of the 1,062 patients (23.2%) receiving any oral triptan were diagnosed with depression, as compared with 16.8% of 18,033 patients not receiving an oral triptan (p <0.001). No difference in the number of patients diagnosed with depression after their first prescription was found between those receiving sumatriptan (4.2%) and those receiving naratriptan or zolmitriptan (3.9%, p = 0.87).

Physostigmine was associated with immediate depressive symptoms in nine normal volunteers administered high intravenous doses.[76] Whether the results of this study apply to patients with myasthenia gravis who take oral physostigmine is unknown. Sodium oxybate has been associated with depression, suicidal ideation, and suicide in controlled and uncontrolled clinical trials for sleep disorders as well as in postmarketing case reports.[77-79] In a 12-month open-label study, depression was reported in 10% of patients.[79] Tetrabenazine is associated with new onset or worsening depression in up to 15% of patients treated for chorea or other movement disorders.[80]

In placebo-controlled trials of 4,400 patients, varenicline was associated with a higher risk of depression than placebo.[81] However, patients with a history of psychiatric disorders were excluded from these trials. A postmarketing analysis of the FDA Adverse Event Reporting System found increased odds of suicidal/self-injurious behavior or depression associated with varenicline treatment compared to nicotine replacement therapy (OR 8.4, 95% CI 6.8–10.4).[81] Although smoking cessation may be associated with nicotine withdrawal symptoms including depression and agitation, there appears to be an increased risk of these symptoms associated with varenicline, because some of these cases occurred while patients were still smoking.[81,82] Several large cohort trials have been conducted to help clarify risks associated with varenicline. A large cross-sectional database study of 12,159 patients who were prescribed varenicline was performed, in which questionnaires were sent to participants' primary care physicians to ascertain adverse effects.[83] There were 103 reports of depression occurring during treatment (1%); there was no control group in this study. A retrospective cohort study of 35,800 individuals in the Department of Defense database did not reveal an increased incidence of depression associated with varenicline compared to nicotine replacement therapy.[84] An additional cohort study in the UK also did not find evidence of increased self-harm, suicidal ideation, or initiation of antidepressant therapy in patients taking varenicline.[85] A New Zealand cohort study of 3,415 patients prescribed varenicline reported new or worsening depression in 2.98%.[86] In another large retrospective cohort of 164,766 patients the hazards of new depression actually decreased in association with varenicline.[87] Two prospective, randomized, placebo-controlled studies of varenicline have been performed. In 525 smokers with a past or current history of depression, the incidence of depression associated with varenicline was similar to that of placebo.[88] A much larger study (n = 8144) was conducted in patients with and without pre-existing psychiatric conditions. Patients were assigned to receive therapy with a nicotine patch, varenicline, or bupropion. There was a larger incidence of psychiatric adverse effects in the psychiatric cohort than the nonpsychiatric cohort (5.8% versus 2.1%, p <0.001) but no difference between the treatment groups, either overall or within the cohorts.[89] It appears that the incidence of depression with varenicline is low; however, the FDA requires warnings about depression in the product information for this drug.

HORMONAL AGENTS

The prevalence of drug-induced depression associated with hormonal agents ranges from 1% to 54%. Agents that affect sex-steroid hormone production appear to be associated with significant risks for inducing depression. Gonadotropin-releasing hormone (GnRH) agonists induce a profoundly hypoestrogenic state and are associated with significant depressive symptoms in approximately 50% of patients.[90-95] Tamoxifen, an antiestrogenic agent, does not appear to confer the same risk. Depression as an adverse effect of tamoxifen was not supported by early placebo-controlled trials in patients with breast cancer.[96] However, several published reports suggest that depression may occur in up to 15–20% of tamoxifen-treated patients with breast cancer and that it is often overlooked or erroneously attributed to the illness.[97-99] These reports do not control for confounding factors, such as the effects of the illness, diagnosis, or adverse effects of chemotherapy, and may overestimate the incidence of tamoxifen-induced depression. The Breast Cancer Prevention (P-1) Study of the National Surgical Adjuvant Breast and Bowel Project provided additional controlled data regarding the association between tamoxifen and depression.[100] The P-1 study was a multicenter randomized, double-blind, placebo-controlled chemoprevention trial in which 11,064 women were assigned to receive tamoxifen or placebo for 5 years. The frequency of depression, as assessed by the CES-D, was similar in both groups during the first 36 months of the trial. The presence of risk factors at baseline including history of depression, current or previous treatment with an antidepressant, or extended periods of dysphoric mood (≥12 months) was associated with significant depressive symptoms regardless of treatment arm.[101]

Aromatase inhibitors (anastrozole, letrozole, exemestane) have been commonly associated with depression in clinical trials for treatment of breast cancer.[102] In a retrospective cohort study from the National Health Insurance Research Database in Taiwan, 35,586 breast cancer survivors receiving adjuvant therapy were observed for up to 6 years to determine the incidence of new onset depression.[103] Overall, 3.67% of the population were diagnosed with depression. Both tamoxifen (adjusted HR 1.45, 95% CI 1.11–1.91) and aromatase inhibitors (HR 1.36, 95% CI 1.19–1.55) were identified as independent risk factors for developing a depressive disorder.

Although depression is the most commonly cited reason for discontinuing therapy with oral contraceptives (OCs), the literature does not provide overwhelming evidence of significant OC-induced depression.[104] The Royal College of General Practitioners' Oral Contraception Study reported that depression occurred at a rate of 70 per 1,000 person-years in women taking OCs. This is similar to the expected rate of affective disorders in females in the U.S.-based Epidemiologic Catchment Area studies.[185] Moreover, the rate of depression in women receiving low-dose estrogen (≤35 mcg) was similar to that observed in the control group, suggesting that commonly used low-dose preparations do not carry an increased risk of depression. More recent evaluations have focused on affective changes rather than on identifying a depressive syndrome or disorder. A review of 13 controlled, prospective studies evaluated affective changes during OC treatment and concluded that women taking OCs experience less variability in affect across the menstrual cycle and less negative affect during the time of menstruation.[105]

Finasteride, a competitive inhibitor of 5 α-reductase that inhibits peripheral conversion of testosterone to dihydrotestosterone, is associated with treatment-emergent depression, although the prevalence is unknown. In a prospective study of 128 men initiated on finasteride for androgenic alopecia, depressive symptoms as measured by the BDI were noted during the first 2 months of treatment. However, this change was clinically insignificant, and no patient reported more than mild symptoms.[106] A case-control study demonstrated that 61 men who formerly used finasteride and experienced persistent sexual adverse effects had higher rates of depression and suicidal thoughts than a control group receiving no treatment for male pattern baldness. Depression, measured with the BDI-II, was present in 75% of former finasteride users versus 10% of controls and suicidal thoughts were present in 44% versus 3%.[107] The rate of depression may have been increased in relation with the presence of sexual side effects.

Drugs that affect the hypothalamic-pituitary-adrenal (HPA) axis are associated with depression. Corticosteroids have been associated with significant psychiatric adverse effects, including depression, mania, and psychosis.[108] The occurrence of severe depression in patients taking corticosteroids is supported by case reports.[109,110] Data from case series, observational studies, and controlled trials also support an association with depression. However, many of these reports fail to quantify the prevalence of significant depressive symptoms.[108,111,112] The largest observational study, the Boston Collaborative Drug Surveillance Program, found that severe psychiatric symptoms, including depression, were relatively uncommon (1.3%) in patients without a psychiatric history who were taking low doses of corticosteroids (<40 mg/day prednisone equivalents).[113] However, the incidence increased to 18% in patients taking >80 mg/day prednisone equivalents. A cross-sectional study in patients with chronic obstructive pulmonary disease reported significantly higher self-reported depression scores in the corticosteroid-using group compared with patients who were not taking corticosteroids.[111] Furthermore, in a short-term prospective cohort study of medical inpatients, corticosteroid exposure was associated with a threefold increased risk of incident depressive symptoms.[114]

IMMUNOLOGIC AGENTS

Several medications used in immunotherapy and cancer chemotherapy, including interferon alfa (INFα), interferon beta (INFβ), tumor necrosis factor alpha (TNFα) inhibitors, and interleukin (IL)-2, are associated with depression. In addition, the immunosuppressant agent mycophenolate was reported to cause depression in a patient using the drug for myasthenia gravis.[115] Multiple INFαs are available: recombinant INFα-2a; recombinant INFα-2b; INFα-n3, a mixture of at least 15 different INF subtypes produced from human leukocytes; peginterferon alfa-2a, a combination of recombinant INFα-2a and an inert 40kD polyethylene glycol polymer; peginterferon alfa-2b, a combination of recombinant INFα-2b and an inert 12-kD polyethylene glycol polymer; and INF alfacon-1 (consensus INF), a recombinant synthetic product. Depression has been reported in association with each type of INFα.[116-124] Several trials investigating the relationship between depression and the various INFαs have been conducted, with treatment-emergent depression reported in 16–96% of patients.[116-145] Although none of these trials were placebo-controlled, many used standardized instruments to assess depression. One study examined the effect of INFα over time and found decreased numbers of patients with depression after 6 months of therapy (8–33%) as compared with 1 month (79–96%, $p = 0.03$).[118]

Two INFβs are available in the United States for treatment of multiple sclerosis: INFβ-1a (intramuscular or subcutaneous injection) and INFβ-1b for subcutaneous administration. Peginterferon beta-1a is also available. The data regarding INFβ-precipitated depression are less clear than those for depression induced by INFα. Two controlled trials suggest an increased risk of depression associated with INFβ-1a, with incidences ranging from 20% to 33%.[125,126] Two other studies of INFβ-1a, have not revealed an increased incidence of depression compared with that associated with placebo.[127,128] Only one trial compared two commercially available formulations of INFβ-1a. The Evidence for Interferon Dose-Effect: European-North American Comparative Efficacy study assigned 677 patients receiving either INFβ-1a 44 mcg subcutaneously three times weekly or INFβ-1a 30 mcg intramuscularly weekly for 24 weeks.[129] No difference in the incidence of depression between the two treatment groups was reported (17% versus 18%, respectively).

A long-term seminal trial of INFβ-1b demonstrated higher rates of depression associated with the clinically used 8 million international units dose compared with those associated with placebo at each yearly timepoint.[130] Two trials have been conducted with the objective of assessing rates of depression associated with INFβ-1b. One study reported depression in a mean (±SD) 13 ± 4% of patients, although no formal testing for depression was performed.[131] Another small study found a decreasing rate of reported depression over the 1-year study period, from 21.4% of patients at baseline to 6.3% of patients at 12 months.[132] Only one study comparing two INFβ products examined depressive symptoms. The Independent Comparison of Interferon trial noted depression in 18 of 88 (22%) of patients administered INFβ-1a 30 mcg intramuscularly weekly and in 18 of 94 (19%) who received INFβ-1b 8 mcg subcutaneously every other day ($p = 0.68$).[133] A prospective cohort of 182 patients initiated on any INFβ treatment was administered the Hamilton Rating Scale for Depression and the BDI at baseline and after a mean treatment duration of 65.6 months. There was no increase in the number of patients demonstrating depression over this time.[134] A Canadian database analysis of antidepressant prescription claims for patients with multiple sclerosis failed to detect a significant difference in the percentage of patients receiving antidepressant prescriptions between those treated with INF and those who received glatiramer acetate. However, the proportion of patients in all cohorts receiving antidepressant medications was high (40%).[135] An Internet-based survey of 2,457 patients with multiple sclerosis collected self-reported information and administered the Patient Health Questionnaire depression module short version to participants.[136] Compared to those who were on no therapy, the risk of depression was higher in patients taking INFβ (OR 1.47, 95% CI 1.07–2.02).

TNFα inhibitors have been reported to cause depression. Case reports of worsening depression and suicidal behavior in patients taking adalimumab, etanercept, infliximab, and ustekinumab have been published.[137-140] In one very small study of 16 patients with ankylosing spondylitis, the number of patients with depression as measured by the Hospital Anxiety and Depression Scale (HADS) and the BDI decreased with ongoing treatment.[141] Similarly, in a study of 92 patients with Crohn disease, infliximab therapy was associated with a decreased incidence of depression as measured by the HADS.[142]

IL-2 has been reported to cause depression. In two studies of patients with metastatic carcinoma, those administered IL-2 were significantly more likely to have depression than those not receiving IL-2 therapy.[143,144] The association between other cancer chemotherapy agents and depression is more tenuous. One trial examined two regimens for the treatment of small-cell lung carcinoma in 77 patients.[145] Regimen 1 consisted of methotrexate, doxorubicin, lomustine, and cyclophosphamide. Regimen 2 comprised cyclophosphamide, doxorubicin, vincristine, and lomustine. Patients were tested with the Profile of Mood States rating scale at baseline and after completion of therapy. Increased depression ratings following therapy were reported in 30% (not statistically significant compared with baseline) of those receiving regimen 1 and 48% ($p = 0.03$ compared with baseline) of those receiving regimen 2. The authors speculated that the increased depression rating scores in patients who received regimen 2 may be attributable to vincristine. A case report also implicates vincristine as a cause of depression.[146] A patient treated for acute myoblastic leukemia who received vincristine 10 mg instead of 1 mg experienced severe depression with uncontrollable crying. The symptoms dissipated over a 3-week period following the overdose.

RETINOIC ACID DERIVATIVES

Several literature sources suggest a possible association between isotretinoin and depression. There have been a relatively large number of reports of isotretinoin and serious depression submitted to the FDA, documenting a temporal relationship between isotretinoin use and onset or worsening of depression.[147] In addition, cases of positive dechallenge with discontinuation of isotretinoin therapy and initiation of psychiatric treatment and positive rechallenge have been reported.[148-150] These reports have led to several types of trials examining the potential link between isotretinoin use and depression; however, no randomized, controlled studies have been performed. Conflicting reports from retrospective studies found either a relative risk of 2.68 (95% CI 1.10–6.48) for depression associated with isotretinoin use or no increased risk of depression or suicide.[151,152] Several prospective studies have assessed patients prescribed isotretinoin using various depression scales. These trials enrolled between 33 and 126 patients. Although some studies reported significant worsening in depression scores over time with isotretinoin, others saw no change in depression, and others demonstrated statistically significant improvements in mood.[153-160] Four prospective, controlled studies have been performed comparing isotretinoin to other treatments. In the first prospective, case-controlled study, 100 patients treated with isotretinoin were compared to 100 patients treated with topical acne cream or oral antibiotics.[161] This study used two depression scales and collected information on the severity of acne, social support, stress, and family history as potential confounders. Depression developed in two patients treated with isotretinoin, but the difference between the two groups was not statistically significant.[161] A second prospective, controlled study administered isotretinoin 1 mg/kg/day or vitamin C to 46 patients.[162] There was no difference between the groups in scores on the BDI. The third prospective, controlled study compared 75 patients administered isotretinoin to those treated with topical antibiotics or retinoids.[163] The HADS and BDI were administered at baseline, month two, and month four following initiation of therapy. Improvement in mood occurred over time. The fourth prospective, controlled study included 190 patients in three arms: one group treated with isotretinoin, one group administered antibiotics with or without a topical cream, and the third group included individuals of similar age who did not have acne.[164] Compared with baseline, there was no difference in CES-D scores after 6 months of treatment. It should be noted that prospective trials have been underpowered to detect changes in depression risk if the true incidence is low. Despite the lack of consensus in the literature, the product labeling for isotretinoin contains a warning about depression and other neuropsychiatric effects. Therefore, many healthcare providers prescribe isotretinoin with caution and consider depression a substantial risk associated with this drug.[165]

Several other drugs not discussed above have been implicated in causing depression in postmarketing case reports, but a causal association has not been established. These include 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins), histamine$_2$ receptor blockers, amiodarone, nonsteroidal anti-inflammatory drugs, metoclopramide, ondansetron, psychostimulants, and monteleukast.[166-182]

MECHANISMS

Drug-induced depression occurs through several mechanisms, including direct alteration of bioamine function, disturbance of HPA axis function, dramatic hormonal changes, and elevation of cytokine production (**Table 18-2**).

Table 18-2 Mechanisms of Drug-Induced Depression

Drug	Mechanism
Clonidine	Reduces norepinephrine output via α_2-adrenergic receptor agonism
Cortisone	Elevates plasma cortisol concentrations
Digitalis	Inhibits central nervous system synthesis of norepinephrine
Efavirenz	Increases proinflammatory cytokines IL-1β and TNFα[a]

Guanethidine	Depletes neuronal norepinephrine
INFα	Increases interleukin-6 production
Isotretinoin	Alters dopaminergic, serotonin, and possibly norepinephrine systems
Leuprolide	Reduces both estrogen and androgen production
Methyldopa	Partial agonism of norepinephrine receptor
Phenobarbital	Reduces plasma unbound tryptophan, which influences serotonin
Reserpine	Depletes neuronal norepinephrine, serotonin, and dopamine
Tamoxifen	Reduces estrogen function via antagonism of estrogen receptors
Tetrabenazine	Depletes neuronal norepinephrine, serotonin, and dopamine
Tiagabine	GABA modulation
Topiramate	GABA modulation
Vincristine	Prevents the conversion of dopamine to norepinephrine
Varenicline	$\alpha_4\beta_2$-nicotinic receptor agonist, indirectly modulates dopamine

GABA = gamma-aminobutyric acid, IL = interleukin, INF = interferon, TNF = tumor necrosis factor.

[a] Animal data.

The antihypertensive agents reserpine, guanethidine, and methyldopa all induce depression likely by depleting CNS bioamine activity.[185] Guanethidine and reserpine deplete norepinephrine at the synapse. Methyldopa is transformed into α-methyl norepinephrine, which is less active than norepinephrine and replaces it at the sympathetic nerve endings, thus acting as a false neurotransmitter. Tetrabenazine, a monoamine depleter used for hyperkinetic movement disorders, depletes central norepinephrine, dopamine and serotonin.[80] Notably, the norepinephrine depletion caused by reserpine generated one of the early theories of the pathogenesis of depression (e.g., the monoamine hypothesis).[186,187] Clonidine also reduces central norepinephrine output via stimulation of α_2-adrenergic receptors.[188]

The mechanism of digoxin-induced depression is unknown, although alteration of CNS norepinephrine synthesis is suspected. In animal models, digitalis has been shown to inhibit CNS synthesis of norepinephrine and to decrease norepinephrine uptake by CNS tissue, with an apparent overall activation of CNS noradrenergic function. Altered activity of CNS dopaminergic and serotonergic systems also has been demonstrated, particularly in association with high digitalis doses.[36] Similarly, the mechanism of isotretinoin-induced depression is not clear, but animal studies suggest alterations in the dopaminergic, serotonin, and possibly norepinephrine systems.[154,189]

GnRH agonists induce a hypogonadal state, resulting in a significant reduction in both estrogen and androgen production. Significant fluctuation in serum estrogen concentrations and low estrogenic states have been associated with substantial mood symptoms in patients with premenstrual dysphoric disorder and during menopause. The significant decline in estrogen production associated with GnRH agonist therapy is believed to be the cause of depressive symptoms in these patients. Estrogen may affect mood in several ways, such as by increasing the availability of neurotransmitters, including serotonin, through enhancement of the degradation of monoamine oxidase.[190] Estrogen modulates serotonin in other ways, including regulation of tryptophan, a serotonin precursor, and increasing the number of serotonin transport sites.[191] Tamoxifen, an estradiol receptor antagonist, also may produce depressive symptoms caused by a decline in estrogen function. However, raloxifene, a selective estradiol receptor antagonist without CNS activity, does not appear to induce depression.[192]

A number of mechanisms have been proposed regarding the mood effects of OCs. Estrogen may induce pyridoxine deficiency resulting in a decrease in serotonin and gamma-aminobutyric acid (GABA) concentrations in the CNS.[193] Other possible mechanisms include estrogen- and progesterone-mediated augmentation of GABA's inhibition and suppression of glutamate, and progesterone-mediated increase in monoamine oxidase activity.[194]

Corticosteroids are believed to induce mood symptoms by elevating plasma cortisol concentrations. Patients with Cushing syndrome have been reported to have high rates of depressive symptoms.[195] Moreover, abnormalities of the HPA axis due to hypercortisolemia are found in patients with MDD.[196] However, corticosteroids are as likely to induce mania as depression, suggesting a complex interaction.[109]

The mechanism of AED-induced depression likely involves GABA, an inhibitory neurotransmitter, alterations in serotonin activity, or a combination of these effects. Some evidence suggests that antidepressant agents enhance activity at GABA-B receptors and decrease activity at GABA-A receptors.[197] Therefore, agents that primarily act at the GABA-A receptors (phenobarbital, tiagabine, or topiramate) or that indiscriminately increase the amount of GABA available to both receptors (tiagabine) may be associated with greater potential for inducing depression. Both phenobarbital and phenytoin reduce unbound plasma tryptophan concentrations, which influences serotonin turnover.[198] In addition, the enzyme-inducing AEDs can cause a folate deficiency. Decreases in plasma folate concentrations may reduce methylation reactions involving neurotransmitters and monoamines, which may be implicated in depression induction.[199]

Mechanisms of depression caused by the immunologic agents have not been elucidated completely. Most work in this area has been conducted with INFα, and several mechanisms have been proposed that may be applicable to INFβ and IL-2. INFα induces the production of proinflammatory cytokines, such as IL-6, which may lead to depression.[119] An increase in the Montgomery–Asberg Depression

Rating Scale (MADRS) scores was significantly and positively correlated with increases in serum IL-6 concentrations.[118] INFα increases serotonin transporter messenger ribonucleic acid and uptake activity, reduces serotonin concentrations in brain or serum, and induces the catabolism of tryptophan.[119] The net effect of these alterations in the serotonin system is to decrease the amount of serotonin at the active receptor sites and potentiate depression. INFα administration is also associated with HPA activation,which has been associated with depression and with increases in serum IL-6 concentrations.[119,200,201] Thus, it is unclear mechanistically why anti-TNF monoclonal antibodies might cause depression.[141] In fact, infliximab has been studied to relieve treatment-resistant depression,[202] particularly in patients with elevated baseline inflammatory biomarkers.[203] Depletion of tryptophan, the amino acid precursor to serotonin, caused by INFα administration has also been hypothesized.[204] Polymorphisms of the allele coding for the 5-HT_{1A} receptor have also been implicated in the development of INFα-induced depression.[204,205] Efavirenz has been shown in rat models to increase concentrations of pro-inflammatory cytokines IL-1β and TNFα, which may be linked to depression.[206]

Vinca alkaloids inhibit the transport of dopamine hydroxylase, thereby preventing the conversion of dopamine to norepinephrine,[146] possibly resulting in depression. The mechanism of varenicline-induced depression is unknown, but the partial α_4-β_2-nicotinic receptor agonist indirectly modulates dopamine,[207] which may in turn modulate mood.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The key feature of diagnosis is the temporal association between the development of depressive symptoms and the use of a causative drug. The disturbance of mood or presence of depression should be severe enough to result in impairment of daily function. In addition, the clinician must rule out the possibility of pre-existing depression and the influence of the disease state being treated, particularly psychological stressors.

Symptoms associated with drug-induced depression (**Table 18-3**) are similar to those observed in patients with MDD, with few exceptions. More severe symptoms including suicidal ideation and psychosis have been reported in association with INFα, corticosteroids, and varenicline.[82,109,113,120] With most agents, the onset of depression generally occurs during the first weeks of treatment. The median onset of symptoms in FDA-reported cases of isotretinoin-associated depression during the first course of therapy was 30 days, and the median recovery time was 4.5

days.[150] During the rechallenge course, the time to onset of symptoms was shorter.[208] In patients treated with GnRH agonists, the onset of depressive symptoms is consistent with the time to reach a hypogonadal state.[90,91] When the hypogonadal state is of short duration, as with in vitro fertilization treatment, depressive symptoms are transient and less severe.[95] During sustained treatment for endometriosis, depressive symptoms appear to be persistent and generally more severe, sometimes resulting in the need for discontinuation of treatment.[92,96,209] Drug-induced suicidality is temporally associated with initiation of treatment and represents a marked change in thoughts and behavior from baseline.[74] Suicidality associated with anticonvulsants and antidepressants occurs early in treatment, and must be distinguished from the underlying mood disorder for which they were prescribed.

Table 18-3 Signs and Symptoms Associated with Drug-Induced Depression

- Depressed mood
- Diminished interest or pleasure in most activities
- Sleep changes (insomnia or hypersomnia)
- Appetite increase or decrease
- Hopelessness/helplessness
- Suicidal ideation
- Fatigue
- Diminished ability to concentrate
- Psychomotor agitation or retardation

Conditions and diseases associated with depression must be ruled out to arrive at a diagnosis of drug-induced depression (**Table 18-4**). The incidence of depression in patients with epilepsy ranges from 4% to 62%, depending on the method of diagnosis and the population studied.[210,214] One study found that patients with hypertension were three times more likely to have depression than normotensive patients.[212] Many chronic health conditions for which immunologic agents are used have been associated with high rates of depression. The prevalence of depression in patients with chronic hepatitis C is 11–30%, while the prevalence of depression in patients with cancer is 28%.[213,214] Multiple sclerosis is also associated with a 15–30% point prevalence of depression and a lifetime depression incidence of 40–60%.[215] Fatigue, a symptom common to all of the disease states in this category, often can be confused with depression. Alternatively, depression may be underdiagnosed because of the expectation that patients will present with fatigue. Other conditions that may cause misdiagnosis of depression include hyperthyroidism or hypothyroidism and unrealistic expectations, leading to discouragement and frustration.[216]

Table 18-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Depression

- Substance-use disorder
- Pre-existing mood disorder
- General medical conditions
  - Endocrine (e.g., diabetes, hypothyroidism)
  - Infections, human immunodeficiency virus
  - Anemia, folate deficiency
  - Collagen disorders (e.g., systemic lupus erythematosus, scleroderma, rheumatoid arthritis)
- Neurologic disorders (e.g., epilepsy, multiple sclerosis, Parkinson disease)
- Cardiovascular and respiratory disease
- Malignant disease

RISK FACTORS

Female sex, family history of mood disorder, childhood abuse, anxiety disorders, sleep disorders, and neurologic disorders are known risk factors for MDD.[1] It is unclear, however, whether these factors also increase the risk of drug-induced depression. Much of the literature regarding drug-induced depression arises from case reports, database evaluations, and observational studies, which are not designed to identify risk factors. Factors that appear to increase the risk of drug-induced depression are listed in **Table 18-5**.

Table 18-5 Risk Factors for Drug-Induced Depression

Risk factors common to all drugs

- History of major depressive disorder or prior depression episode
- History of drug-induced depression
- Psychosocial stressors (e.g., financial, relationship, or job stress)

Risk factors associated with specific drugs

- Corticosteroids
  - Dose (>80 mg/day prednisone equivalents)
- Efavirenz
  - Plasma concentrations >2.74 mcg/mL during long-term treatment
- Topiramate
  - Dose (higher starting dose of 50 mg/day, titration of 50 mg/day every 2 weeks)
  - Temporal-lobe epilepsy with hippocampal sclerosis
  - Presence of cognitive adverse effects
  - Family history of epilepsy

    - History of febrile seizures
- INFα
    - Homozygous for the HTR1A-1019G allele
    - Increased immune activation (e.g., increased soluble IL-2 receptor, IL-6, and IL-10 serum concentrations) prior to treatment for hepatitis C
- Oral contraceptives
    - History of premenstrual depression or pregnancy-related depression
    - History of dysmenorrhea
    - Family history of depression while taking oral contraceptives
    - Predisposition to vitamin B_6 deficiency
    - High degree of psychological distress prior to oral contraceptive use
    - Age <20 years experience negative affect more often
    - High estrogen/progesterone content

HTR1A = 5-hydroxytryptamine receptor 1A, IL = interleukin, INF = interferon.

A history of depression or another psychiatric disorder is the most consistently identified risk factor for depression associated with most of the causative drugs. In addition, the presence of psychological stressors has been noted to increase the risk. Although increased stress may be expected in patients with serious medical illnesses, it is unclear whether increased stress increases the risk of depression associated with drugs such as immunologic or cancer chemotherapy agents. Patients with a history of drug-induced depression are likely to be at greater risk upon repeated exposures.[28]

Dose may be an important risk factor for depression associated with some drugs. Depression is more likely to occur when higher doses of corticosteroids are used (>80 mg/day prednisone equivalents).[114] It is unclear whether multiple courses of corticosteroids increase the risk of depression. However, patients with a history of corticosteroid-induced depression should be monitored closely. Likewise, OCs with higher estrogen content are more commonly associated with depression. Some open-label data suggest that the risk of neuropsychiatric adverse effects associated with long-term treatment (>6 months) with efavirenz were more than five times greater in patients with plasma efavirenz concentrations >2.74 mcg/mL.[217] One case of levetiracetam-induced depression was likely dose-associated.[218] A small study that compared low- and high-dose INFα also showed increased rates of depression with the higher dose.[120]

A prospective, cross-sectional study determined a gene association with depression induced by isotretinoin. The T allele at the *rs9303285* gene encoding the retinoic acid receptor alpha was linked to an approximately 40% risk of isotretinoin-associated depression.[154]

Several factors have been associated with an increased risk of treatment of emergent depression or negative affect in patients taking OCs (Table 18-5). Whereas the overall risk for depression caused by these drugs is considered low, patients presenting with any of these factors should be considered at greater risk. The risk may vary with the type of OC used. Monophasic OCs exert greater mood-stabilizing effects than triphasic products. In addition, patients with premenstrual mood symptoms may have an increased risk of negative mood effects with OCs containing low amounts of progesterone or a low progesterone-to-estrogen ratio. Women without premenstrual mood symptoms appear to have increased risk with a higher progesterone content.[108]

A retrospective study of patients with temporal lobe epilepsy who were initiated on topiramate therapy revealed that those with hippocampal sclerosis in association with temporal-lobe epilepsy were significantly more likely to develop depression than those without hippocampal sclerosis. Patients without hippocampal sclerosis who had cognitive adverse effects such as psychomotor slowing or word-finding difficulties associated with topiramate were also more likely to be diagnosed with depression.[219] A case series of patients initiated on topiramate therapy found that a higher starting dose (50 mg daily) and a faster titration schedule (increase of 50 mg/day every 2 weeks) as well as the presence of cognitive adverse effects caused by topiramate increased the odds of any psychiatric adverse event, including depression. Other related factors were family or personal history of psychiatric conditions, family history of epilepsy, and a history of febrile convulsions.[53] One small study of women with epilepsy found that the odds of development of postpartum depression was increased with multiparity (OR 12.5, 95% CI 1.9–82.7) and AED polytherapy (OR 9.3, 95% CI 1.5–58).[220] However, no specific AED was implicated. One retrospective study of topiramate demonstrated a five-fold increased risk of depression in patients who initiated treatment with rapid titration.[221]

Risk factors for depression associated with INFα treatment include younger age, poor baseline sleep, hepatitis C, and an increase in vegetative symptoms of depression on the Zung depression rating scale after 4 weeks of treatment.[222-225] A polymorphism (C1019G) on the allele coding for the 5-HT$_{1A}$ receptor (HTR1A) has also been implicated in the development of INFα-induced depression.[205,226] Patients who were homozygous for the HTR1A-1019G allele had an approximate threefold increased risk of depression induced by INFα.[227] The HTR1A receptor is the major auto-receptor on the serotonergic raphe neurons. Alterations in this receptor can lead to decreased secretion of serotonin. This polymorphism is relatively common, with approximately 48% of people having at least one C1019G allele. This finding may help explain the very common occurrence of depression in patients treated with INFα.[205] One small study of 16 patients undergoing treatment with various INFα regimens for hepatitis C found that patients with higher levels of immune activation as demonstrated by increased soluble IL-2 receptor, IL-6, and IL-10 serum concentrations prior to treatment were more likely to have major depressive disorder as measured by *DMS-IV* criteria and the MADRS score.[228] A small study of 50 patients with hepatitis C found that the hepatitis C virus genotype 1 was associated with a 2.1 greater odds of developing INFα-associated depression.[229] Conversely, a separate cohort study of 278 patients with hepatitis C determined that hepatitis C virus genotype 2 was associated with a higher risk of developing depression with INFα treatment (OR 2.27, 95% CI 1.07–4.78).[222]

The risk for suicidality associated with antidepressants is inversely related to age, with patients <18 years at greatest risk, and adults 18–24 years at greater risk than older adults (25–64 years).[74] Antidepressant selection, dose, or indication do not significantly change the risk of suicidality within the stratified age groups. Conversely, patients receiving an AED for epilepsy are at greater risk for suicidality than patients with psychiatric disorders (OR 3.53, 95% CI 1.28–12.1).[74]

MORBIDITY AND MORTALITY

Drug-induced depression can be associated with significant morbidity and mortality. Many drugs associated with depressive symptoms are used to treat chronic medical disorders or are components of lifesaving or life-prolonging therapeutic regimens. Patients experiencing significant depressive symptoms as a result of their treatment may be less likely to adhere to therapy and may be less optimistic about potential treatment benefits. Furthermore, the development of severe depressive symptoms may necessitate the discontinuation of life-prolonging treatments.

The presence of depression or severe depressive symptoms may increase the risk of suicide or suicidal ideation. Although the prevalence of suicide risk in patients with drug-induced depression is unknown, up to 15% of patients with severe MDD die as a result of suicide.[1] Moreover, patients with MDD have decreased physical, social, and role functioning as well as increased pain and physical illness.[230] The risk of suicidality associated with antidepressant treatment must be balanced with the much greater risk of suicidality with untreated depression.

PREVENTION

There is very little information available regarding preventive strategies for drug-induced depression. However, some interventions may prove useful (**Table 18-6**). Identifying patients with risk factors (e.g., history of depressive episodes) and implementing a prospective screening and monitoring plan seems prudent, but will not prevent drug-induced depression. Careful monitoring and early detection may, however, minimize the negative sequelae associated with depression. Treating psychosocial stressors with interventions such as counseling and education may also prove beneficial, but this strategy has not been systematically evaluated. One study has examined the role of social support on the development of depression in

127 patients with melanoma who were treated with INFα. Those with more social support had smaller increases in BDI scores during one year of therapy.[231]

Table 18-6 Approaches to Help Prevent Drug-Induced Depression

Assess patient for history of depressive episodes or history of drug-induced depression at baseline. *If yes*:
- Consider individual risk–benefit of drug therapy
- Encourage healthy lifestyle behaviors and supportive therapy
- Pretreat with selective serotonin reuptake inhibitor if undergoing therapy with interferon- or gonadotropin-releasing hormone agonist
- Select alternative drug within therapeutic category, if possible

Pretreatment or prophylaxis for depressive symptoms may be useful in some cases. Sabet-Sharghi reported the successful pretreatment (with lithium and protriptyline) of an individual with a history of corticosteroid-induced depression.[232] In a retrospective review of patients receiving leuprolide for treatment of endometriosis, concomitant therapy with sertraline minimized the emergence of depressive symptoms.[209] Convincing evidence exists regarding the benefits of pretreatment for depression in patients with melanoma receiving INFα. Musselman et al.[233] randomly assigned 40 patients with melanoma to receive pretreatment with paroxetine (n = 20) or placebo (n = 20) 2 weeks prior to and throughout the 12-week INFα regimen. The risk of developing depression was lower in the paroxetine group (11% versus 35%, RR 0.24, 95% CI 0.08–0.93) and pretreated patients were less likely to discontinue INFα because of depressive symptoms (5% versus 35%, RR 0.14, 95% CI 0.05–0.85). Three meta-analyses of patients with hepatitis C found that prophylactic administration of selective serotonin reuptake inhibitors during INFα treatment reduced the incidence of depression compared to placebo.[234-236] Amantadine, a medication with both antiviral and dopaminergic effects, was studied in 14 patients who were treated with peginterferon alfa-2a and ribavirin for hepatitis C. Compared with the control group, amantadine-treated patients were significantly less likely to develop depression by week 24 of treatment.[237] One small placebo-controlled study in patients receiving efavirenz therapy found that HDRS and BDI scores improved in patients who received cyproheptadine 8 mg/day for 1 week followed by 12 mg/day for 3 weeks.[238]

MANAGEMENT

Appropriate management (**Table 18-7**) of drug-induced depression begins with prompt recognition of the emergence of depressive symptoms. In some cases, symptoms may be transient or mild, as in patients receiving GnRH agonist therapy as part of in vitro fertilization treatment.[95] For many patients, education and support may be the only intervention needed. Psychological interventions or psychotherapy are beneficial for patients with mild-to-moderate symptoms of MDD, but the benefit of psychotherapy in patients with drug-induced depression is unclear. For more severe or persistent depressive symptoms, therapy with the offending agent will likely have to be discontinued or antidepressant treatment may need to be initiated, and in some cases, both strategies are required. Children, adolescents, and young adults (18–24 years) receiving antidepressants for depression or other psychiatric disorders should be monitored frequently (weekly to biweekly) during the first few weeks for treatment-emergent suicidality or worsening of depression. The emergence of suicidal ideation or psychotic symptoms should always be considered serious, and these patients should receive immediate intervention, including hospitalization.

Table 18-7 Management of Drug-Induced Depression

- Discontinue the offending agent, if possible
- Substitute medication within therapeutic class
- Counseling or supportive therapy for mild depressive symptoms
- Initiate antidepressant therapy for persistent or moderate-to-severe depressive symptoms

There are insufficient data to recommend specific doses of antidepressant therapy for the treatment of drug-induced depression, although in most reports doses similar to those used in patients with idiopathic depression have been administered. Duration of therapy should be based on patient response and clinical judgment. In cases in which it would be best for a patient to continue to receive therapy with the causative agent, clinicians should consider factors such as severity of presentation, current mood, and level of psychological stress before deciding to discontinue drug therapy.

Although not always possible, in some cases substituting another medication in the same drug or therapeutic class but with a lower risk of causing depression may represent the best management strategy. For example, patients experiencing β-blocker-induced depression may benefit from receiving a hydrophilic β-blocker or an antihypertensive drug from a different class (e.g., ACE inhibitor or diuretic).[239] Similarly, patients experiencing OC-induced depression may benefit from an OC with a lower estrogen content or different estrogen:progesterone ratio. Patients with varenicline-induced neuropsychiatric side effects should be considered for nicotine replacement or bupropion for smoking cessation. One prospective, observational study substituted nevirapine for efavirenz in 116 patients with neuropsychiatric disturbances. Patients had resultant improvement on the HADS without loss of viral suppression.[240]

No specific treatments have been proposed for depression associated with the immunologic agents. Discontinuation of therapy is sometimes considered, but remission of depression does not always occur simultaneously with the discontinuation of interferon.[213] For patients with hepatitis C, selective serotonin reuptake inhibitors may be the best choice for management, as they are well tolerated by patients with liver disease, whereas tricyclic antidepressants with significant anticholinergic effects may increase the cognitive dysfunction that occurs in these patients.[211] Gleason et al.[241] conducted a study using citalopram to treat depression in patients with hepatitis C. Of the 15 patients participating in the trial, four had previously taken INFα and four were currently receiving INFα therapy. Citalopram 10–40 mg/day was administered to all patients with a resultant improvement in mood. In another study, of 13 patients undergoing therapy with INFα who experienced depression, 85% were responsive to treatment with citalopram.[242] Similar results were achieved with citalopram in another study.[227] Bupropion therapy resulted in remission or improvement in nine of ten patients with INFα-associated depression in an open-label study.[243] The authors postulated that the response may be due to anti-inflammatory effects of bupropion.[244] There are case reports of patients with INFα-induced depression who were responsive to treatment with methylphenidate or venlafaxine.[245,246]

Selection of specific INFα therapy based on patients' depressive symptoms has been proposed. For patients with suicidal tendencies, INFα-n3 is preferred, while INFα-2a is suggested for patients experiencing depersonalization. Patients with paranoia may experience fewer symptoms with INFα-2a or INFα-2b, while those patients exhibiting obsessive or compulsive symptoms may improve during treatment with INFα-n1.[193] However, these recommendations are based on relatively small numbers of patients and the symptoms expressed by those individuals require evaluation in a prospective study. Sertraline has proven effective for the management of depressive symptoms associated with GnRH agonists.[90,91,216] Lithium, selective serotonin reuptake inhibitors, and electroconvulsive therapy have been used to manage corticosteroid-induced depression.[109]

There is inherent difficulty in recommending antidepressant therapy for patients with epilepsy because of the epileptogenic potential of most antidepressant drugs. Bupropion may exert proconvulsant properties in persons without epilepsy, particularly in doses >450 mg/day.[247] Tricyclic antidepressants, particularly amoxapine, clomipramine, maprotiline, and mianserin, also may have epileptogenic potential.[199] Although selective serotonin-reuptake inhibitors are generally preferred in patients with epilepsy, they have been associated with seizures in case reports. This may be due, in part, to an increased incidence of hyponatremia.[248]

INFORMATION FOR PATIENTS

Patients should be informed regarding the possibility of the emergence of depressive symptoms when prescribed a drug associated with depression. They should be instructed to report any symptoms of depressed mood or extreme irritability, anxiety, anhedonia, difficulty sleeping, fatigue, feelings of hopelessness or helplessness, change in appetite or weight, or thoughts of death. Patients with a history of depression may be at greater risk for experiencing drug-induced depression. Patients should be encouraged to inform their provider of any history or treatment of any psychiatric disorder.

The FDA requires pharmacists to distribute medication guides to patients receiving medications with specific warnings of suicidality or other severe neuropsychiatric side effects. Medication guides are intended to inform patients about a known serious side effect of a drug. These guides are available at https://www.fda.gov/drugs/drugsafety/ucm085729.htm.

CHAPTER 19

Anxiety

Julie A. Dopheide and Seth Gomez

Each individual, no matter how healthy, has experienced symptoms of anxiety at some point in his or her life. Anxiety can be adaptive and help individuals to prepare and enhance their performance; it also drives one to be more cautious in potentially dangerous circumstances. For example, occasional low-level anxiety can motivate an individual to prepare for an examination, professional presentation, or help one avoid walking alone in a high crime area. In contrast, when persistent anxiety above an individual's tolerability threshold causes undue distress, discomfort, and impairs functioning, it is considered maladaptive and therefore a disorder. If left untreated, anxiety may lead to other conditions, such as depression or alcohol abuse.[1-4] The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*), includes a diagnosis of substance or medication-induced anxiety, a clear indication that medications are an increasingly well-recognized contributor to signs and symptoms of anxiety.[1] A patient presenting with anxiety symptoms should be carefully assessed to determine whether a primary anxiety disorder is present, whether the symptoms are situational, or whether the symptoms are secondary to a drug. A combination of these factors is also possible.[1,4]

CAUSATIVE AGENTS

Drugs that may induce anxiety are listed in **Table 19-1**.[4-80] Drugs from a variety of classes have been implicated as causes of anxiety. These include central nervous system (CNS) agents, cardiovascular drugs, anti-infectives, hormonal products, cancer chemotherapy agents, nonprescription medications and herbal supplements, and illicit drugs, among others. The *DSM-5* diagnostic criteria for substance/medication-induced anxiety involves predominant panic attacks or symptoms of anxiety developing soon after substance intoxication or withdrawal, or after exposure to a medication. To meet the criteria, the symptoms should cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.[1] Individuals who develop anxiety after taking drugs listed in this chapter experience a wide range of symptoms and symptom severity. Individual agents that cause specific symptoms of anxiety are presented when a description of the type of drug-induced anxiety is available.

Table 19-1 Agents Implicated in Drug-Induced Anxiety[a]

Drug	Incidence	Level of Evidence[b]
Amphetamines[4-8,c]	10–50%	A
Anabolic steroids[7,9,73]	10–50%	B
Antipsychotics[10,11]	10–30%	B
Aripiprazole[10,12]	10–20%	B
Armodafinil[50-53,c]	1–10%	A
Atomoxetine[7,56,57]	NK	B
Abacavir[62]	NK	C
Baclofen[7,d]	NK	C
Barbiturates[7,d]	NK	B
Benzodiazepines[6,7,13,14,d]	10–50%	A
β-agonists[64]	NK	B
β-blockers[7,15,16,d]	10–40%	B
Bitter orange (synephrine)[38]	NK	B
Brexpiprazole[76]	2–4%	B
Bupropion[4,7,c]	10–20%	B
	10–30%	A

Caffeine[4,7,17,18,c,d]		
Cannabis[1,19,d]	30–70%	B

Yohimbine[4,7,48,c]	NK	B
Ziprasidone[10,11]	10–20%	B

NK = not known.

[a] For all drugs listed, anxiety may occur during both treatment and withdrawal unless otherwise specified.

[b] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[c] Anxiety only occurs during treatment (not during withdrawal).

[d] Anxiety only occurs during withdrawal (not during treatment).

[e] Anxiety may occur during fluctuations in plasma concentrations.

[f] Includes cigarettes and nicotine replacement therapies (gum, lozenge, inhalers, patches).

CNS-ACTIVE AGENTS

Anxiety is associated with intoxication and withdrawal from drugs of abuse such as cocaine, methamphetamine, and phencyclidine.[4,7] Anxiety is also a well-known effect of stimulating substances such as caffeine, nasal decongestants (e.g., pseudoephedrine), and amphetamines.[1,17,18,35] Stimulant medications including dextroamphetamine, amphetamine, methylphenidate, and dexmethylphenidate have been associated with new-onset or worsening anxiety in susceptible individuals.[4-8] Anxiety is uncommon when these agents are used at recommended doses for attention deficit/hyperactivity disorder (ADHD). In fact, some studies report improvements in anxiety symptoms when patients with ADHD are treated with methylphenidate (children) and mixed amphetamine salts (adults).[31,82] The use of atomoxetine, a nonstimulant medication for ADHD, may prompt early discontinuation due to anxiety symptoms. Atomoxetine-associated anxiety may be particularly problematic in individuals with developmental disabilities or epilepsy.[56,57]

Selective serotonin reuptake inhibitors (SSRIs), serotonin norepinephrine reuptake inhibitors (SNRIs), and some tricyclic antidepressants (TCAs) are effective treatments for anxiety and depressive disorders when used at recommended doses for longer than 4 weeks. It is also important to recognize that new-onset or worsening anxiety is possible during the initiation of treatment, during a dose increase, or after abrupt discontinuation of therapy with these agents.[36]

Anxiety is also common when CNS depressant agents such as barbiturates, benzodiazepines, and opioids are discontinued abruptly after long-term use.[4,13,23,54] Benzodiazepines relieve anxiety via potentiation of γ-aminobutyric acid (GABA), an inhibitory neurotransmitter.[4,23] After 2–4 weeks of treatment with benzodiazepines, receptor dependence develops and significant withdrawal symptoms can occur when a dose is missed or when therapy is discontinued.[4,13,14] Anxiety associated with benzodiazepine withdrawal is frequently described as worse than the pretreatment anxiety for which therapy was initiated. Abrupt discontinuation of high-dose benzodiazepines produces the most severe withdrawal-associated anxiety. Abrupt discontinuation of benzodiazepines with shorter half-lives and no significant active metabolite (e.g., alprazolam) is particularly anxiety-provoking.[13,14]

Carisoprodol, a muscle relaxant, is increasingly recognized for its abuse potential and is now considered a controlled substance (C-IV) in the United States. As more individuals misuse and abuse carisoprodol, the number who experience withdrawal and associated anxiety will also likely increase.[63] Valerian is an herbal product that modulates GABA in the CNS and is used for anxiety and insomnia.[42,75] Symptoms of worsening anxiety and insomnia have been reported after abrupt discontinuation of valerian, suggesting that dependence occurs over time, an effect similar to that associated with benzodiazepines.[42,43]

Certain anticonvulsants may also precipitate drug-induced anxiety symptoms. Gabapentin and pregabalin employ similar mechanisms of action and both are associated with anxiety upon withdrawal of therapy.[7,27,55] Topiramate-induced anxiety can also be problematic at low doses (<100 mg/day) leading to discontinuation or requiring additional treatment in 2–5.5% of migraneurs.[66] Three case reports of topiramate-induced new onset panic attacks occuring 3–6 weeks after intiation have also been described.[67-69]

Varenicline is a selective $\alpha_4\beta_2$-nicotinic acetylcholine partial receptor agonist that is indicated for smoking cessation. During a controlled clinical trial in 250 Asian patients taking varenicline, 5.6% developed anxiety compared with 2.4% in the placebo group.[44] Case reports of insomnia, anxiety, depression, and psychosis associated with varenicline therapy for smoking cessation prompted the U.S. Food and Drug Administration (FDA) to issue a public health advisory in January 2008.[45] More detailed evaluations of the neuropsychiatric effects of varenicline have since been conducted that show the risk of varenicline-associated anxiety may be confined to individuals with pre-existing psychiatric disorders.[70,83] In individuals without pre-existing psychiatric disorders, there was a nonsignificant trend toward increased anxiety associated with varenicline.[70] Available evidence indicates that any person taking varenicline is at risk for treatment emergent anxiety, but this is more likely to occur in individuals with pre-existing psychiatric disorders.

STEROIDS AND HORMONES

Steroids and several hormones have been associated with mood swings, including anxiety. Anxiety is a well-known adverse effect associated with the use of glucocorticoids and anabolic steroids, including nandrolone, oxymetholone, stanozolol, and oxandrolone.[7,9,71] Anxiety provoked by these steroidal agents is less common than rage, aggression, and irritability, but panic attacks and worsening anxiety have all been described.[7,9,71] The steroidal hormones estrogen, progesterone, and testosterone, are associated with anxiety, particularly during fluctuating plasma concentrations that occur in association with certain medical conditions or age-related decline (e.g., hypogonadism, reproductive-age transitions), and from exogenous hormone supplementation or withdrawal.[23,24,72] The severity of anxiety induced by hormone changes is related to sex, individual susceptibility, and the degree of fluctuation in plasma concentrations. For example, estrogen replacement and withdrawal have been linked to worsening anxiety, insomnia, and panic attacks in susceptible women.[7,23,72] A wide range in severity of anxiety symptoms associated with estrogen concentration changes have been reported in premenstrual, postpartum, and perimenopausal women; plasma estrogen concentrations decline before stabilizing at menopausal concentrations.[84,85] Similarly, low concentrations of testosterone in women with age-related decline in androgens and men with hypogonadism may induce anxiety or depression; testosterone replacement in these individuals may improve anxiety symptoms.[86] Furthermore, new onset anxiety occurs in 8.9% of older males treated with the gonadotropin-releasing hormone (GnRH) agonists leuprolide and goserelin for treatment of prostate cancer, emphasizing the role of low testosterone concentrations in the emergence of anxiety symptoms.[28] Dependence and abuse of testosterone and testosterone analogues for recreational use and performance enhancement is also associated with greater self-report of anxiety and anxiety disorders.[9,73] Therefore, anxiety symptoms may occur during times when plasma testosterone concentrations are in excess or deficient and may occur in both women and men.[39,81,87,88] Danazol is an androgen that may be used for the treatment of endometriosis and fibrocystic breast disease. The risk of danazol-induced anxiety and irritability is similar to that associated with leuprolide and goserelin.[7]

Clomiphene is a selective estrogen receptor modulator used to induce ovulation in the treatment of infertility. In a self-reported survey using the State-Trait Anxiety Inventory, 25.9% (n = 162) of patients reported anxiety as an adverse effect of clomiphene, while other possible symptoms of anxiety including forgetfulness and difficulty concentrating occurred in approximately 19% of patients.[49] In the same study, human menopausal gonadotropin use was associated with even higher rates of anxiety; however, anxiety rates were also correlated with the number of years spent trying to conceive. This suggests that the duration of infertility is also anxiety-provoking.[49]

Thyroid hormone supplementation does not routinely lead to anxiety. However, excessive doses may result in emotional symptoms, such as feeling “on edge” or jittery, as well as physical symptoms, including sweating or tachycardia.[4] One study of 40 women with subclinical hypothyroidism describes significantly elevated anxiety scores in 8 of 20 women treated with thyroxine 50–100 mcg/day, as compared with only 1 of 14 women treated with placebo.[74] Thyroid supplements containing triiodothyronine, thyroxine, desiccated thyroid, or tiratricol can cause tachycardia and general anxiety symptoms as well.[75]

ANTI-INFECTIVE AGENTS

Anti-infective agents have been associated with neuropsychiatric adverse effects including anxiety, although the frequency is difficult to predict because of multiple possible mechanisms and confounding variables.[7,26,89] Fluoroquinolones are the class of antibiotic agents associated with the highest incidence of adverse CNS effects, including anxiety and insomnia.[7,26] Efavirenz is the most well-known antiretroviral agent to cause neuropsychiatric effects including anxiety.[60,61] One case report of abacavir-induced anxiety in a pediatric male and postmarketing reports of worsening anxiety associated with raltegravir in patients with pre-existing psychiatric disorders have been documented.[62,80] Although other neuropsychiatric effects may occur, it is uncommon for antiretroviral medications other than efavirenz to induce anxiety.[61]

Antimalarial agents, especially mefloquine, may cause adverse neuropsychiatric effects including depression and anxiety, in children and adults.[29,30,90] In one published case a 10-year-old child experienced feelings of impending doom, panic, a spider phobia, separation anxiety, and multiple physical symptoms of anxiety (hyperventilation, restlessness, insomnia) after taking mefloquine for 2 weeks during a trip to Africa. Symptoms slowly resolved over 1–3 months after the drug was discontinued.[29,30]

OTHER AGENTS

Cancer chemotherapy regimens can provoke a variety of neuropsychiatric effects such as emotional lability associated with ifosfamide, anxiety symptoms induced by vinblastine, or hallucinations and confusion attributed to chlorambucil or cytarabine, respectively. However, intolerable anxiety symptoms are not commonly reported with these agents.[7,46,47]

Angiotensin-converting enzyme inhibitors, β-blockers, statins, and nonsteroidal anti-inflammatory agents (NSAIDs) may cause anxiety.[7,16,34] Among the NSAIDs, indomethacin is associated with the largest number of case reports of treatment-associated anxiety and other psychiatric symptoms.[34] Physical symptoms of anxiety including tremors and tachycardia are a known adverse effect of bronchodilator agents such as albuterol and theophylline. The leukotriene receptor antagonist montelukast, an optional adjunctive treatment for asthma, has been increasingly recognized as an inducer of CNS adverse effects including anxiety, particularly in children, adolescents, and young adults. The increase in reporting is likely related to increased awareness due to a 2008 FDA alert highlighting the behavioral and mood changes associated with montelukast.[65,91] Though montelukast-induced anxiety is possible, the combined effects of concurrent use of inhaled corticosteroids, oral corticosteroids, or β-agonists should also be considered.[65] Irritability attributed to montelukast has also been reported in an adult female with human immunodeficiency virus concurrently taking efavirenz, suggesting a possible interaction between these drugs.[92] Due to the lack of systematic reports and routine assessment for neuropsychiatric adverse effects, it is impossible to determine an incidence of anxiety associated with most of the aforementioned agents.

EPIDEMIOLOGY

Estimates of the relative likelihood of anxiety induced by specific drugs based on available evidence are provided in Table 19-1. The 12-month prevalence of primary anxiety disorders in the general population is provided in **Table 19-2**.[1]

Table 19-2 12-Month Prevalence of *DSM-5* Anxiety Disorders in the General Population[1]

Anxiety Disorder	Prevalence (%)
Substance or medication-induced anxiety disorder	

	0.002[a]
Generalized anxiety disorder	2.9
Separation anxiety disorder	0.9–1.9
Social anxiety disorder	7
Agoraphobia	1.7
Panic disorder	2–3
Panic attacks (isolated)	11.2
Post-traumatic stress disorder[b]	3.5
Obsessive–compulsive disorder[b]	1.2

DSM-V = Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition.

[a] *DSM-5* states the prevalence is likely higher in clinical populations relative to that reported in epidemiological studies.

[b] *DSM-5* has reclassified post-traumatic stress disorder and obsessive-compulsive disorder into trauma and stress related disorders and obsessive-compulsive and related disorders, respectively.

MECHANISMS

For most agents, mechanisms of drug-induced anxiety are poorly or incompletely understood. Possible or probable mechanisms of drug-induced anxiety, where known, are presented in **Table 19-3**.[3-7,18,20,23,35,93] One of the best-understood mechanisms for drug-induced anxiety involves increasing noradrenergic outflow from the locus coeruleus of the CNS. Stimulants, yohimbine, and withdrawal from benzodiazepines or opioids all appear to increase noradrenergic outflow from the CNS.[6,7,23,93,94] Pseudoephedrine, ephedrine, and bitter orange (synephrine) produce dose-related symptoms of anxiety via α_1-adrenergic stimulation that increases nervousness centrally, causing vasoconstriction and a “jittery” or restless feeling. Anxiety associated with withdrawal from carisoprodol is believed to be due to declining concentrations of one of its metabolites, meprobamate, a compound that may activate $GABA_A$ receptors in a manner similar to that of benzodiazepines.[63] Topiramate inhibits the enzyme carbonic anhydrase leading to elevations in central concentrations of CO_2, which is thought to provoke panic symptoms.[67-69] Gabaminergic mechanisms are likely involved when anxiety occurs during abrupt discontinuation of therapy with gabapentin or pregabalin; however, mechanisms of anxiety associated with these anticonvulsants require further study.[27,55]

Caffeine and guarana (an herbal form of caffeine derived from the plant *Paullinia cupana*) exert anxiogenic effects through antagonism of adenosine receptors and the phosphodiesterase enzyme, resulting in excessive neurotransmitter activity.[17,18,23] Anxiety associated with nicotine withdrawal is believed to occur because of a lack of stimulation of dopaminergic reward centers in the brain upon abrupt discontinuation.[6,23] Although overuse of inhalers containing β-agonists such as albuterol can also provoke anxiety symptoms, tremors and anxiety are common in individuals taking these drugs even at normal doses. The likely mechanism is direct stimulation of postsynaptic β-adrenergic receptors causing palpitations, tremors, and the general feeling of anxiety.

Table 19-3 Mechanisms of Drug-Induced Anxiety

Drug	Mechanism
Amphetamines, methylphenidate, stimulants, bupropion, ziprasidone[3-7,35,93,97]	Inhibition of norepinephrine and dopamine reuptake in the presynaptic neuron and stimulation of dopamine receptors
Benzodiazepine withdrawal[4,13,20,23]	Decreased GABA activity and increased noradrenergic outflow from the CNS associated with benzodiazepine withdrawal
Caffeine, guarana, theophylline[4,17,18,20,22,23]	Antagonism of adenosine receptors and phosphodiesterase inhibition
Carisoprodol withdrawal[63]	Decreased GABA activity due to declining concentrations of the metabolite meprobamate
Dopamine agonists and antagonists[20,23,97]	Fluctuating dopaminergic tone in the CNS
Gonadotropin-releasing hormone analogues[28]	Suppresses secretion of gonadotropins LH and FSH from the pituitary gland which leads to decreased production of estrogen or testosterone
Steroidal hormones[23,78,87,a] Estrogen Progesterone	Dysregulation of neurotransmitters in the CNS Estrogen concentration decline causes 5-HT dysregulation Progesterone metabolism modulates GABA
Opioid withdrawal[20,23,54,94]	Decreased opioid receptor activity and increased noradrenergic outflow from CNS
Selective serotonin reuptake inhibitors, serotonin norepinephrine reuptake inhibitors, tricyclic antidepressants[4,20,23]	Neurotransmitter reuptake inhibition (serotonin, norepinephrine, dopamine)
Topiramate[61-69]	Possibly through inhibition of carbonic anhydrase leading to an increase in central CO_2

5-HT = 5-hydroxytryptamine, GABA = gamma-aminobutyric acid, CNS = central nervous system, CO_2 = carbon dioxide, LH = luteinizing hormone, FSH = follicle-stimulating hormone.
[a] Anxiety may occur during fluctuations in plasma concentrations.

Withdrawal from levodopa therapy may trigger a plethora of nonmotor symptoms including anxiety in people with Parkinson disease. Off periods, including early mornings, appear to be associated with higher rates and greater severity of anxiety symptoms due to the decline of dopamine concentrations in the brain.[58,59,95] Interestingly, use of dopaminergic agonists, such as rotigotine and pramipexole, may be associated with fewer nonmotor symptoms compared to levodopa formulations due to their longer duration of action.[58,59,96] However their impact on reducing anxiety symptoms has not been determined. Withdrawal of therapy with dopaminergic agonists or administration of dopaminergic antagonists can cause significant functional-impairing anxiety in individuals with dopaminergic deficits caused by Parkinson disease.[7,96]

Antipsychotics and antidepressants may induce akathisia on initiation and during dose titration. Antagonism of dopamine receptors in the nigrostriatal tract associated with first-generation antipsychotics such as haloperidol, or second-generation antipsychotic agents including risperidone, ziprasidone, aripiprazole, brexpiprazole, and cariprazine can lead to extrapyramidal effects including akathisia, which is a subjective feeling of inner restlessness. Akathisia is frequently accompanied by, or described as, an intolerable feeling of anxiety.[10,12,76,77] Furthermore, aripiprazole, brexpiprazole, and cariprazine act to some degree as partial dopamine agonists at dopamine receptors leading to behavioral activation and anxiety in some individuals. In general, antipsychotic agents that block dopamine receptors but exert no significant anticholinergic blockade are more likely to cause anxiety or akathisia. Additionally, ziprasidone inhibits the reuptake of norepinephrine and serotonin to a degree similar to that of the TCA imipramine, which may initially exacerbate anxiety symptoms in susceptible individuals.[97] Neurotransmitter reuptake inhibition with SSRIs, SNRIs, and TCAs can precipitate anxiety due to acute changes in neurotransmitter activity that occur during intiation of therapy or a dose increase, and can also occur during abrupt discontinuation of therapy leading to withdrawal symptoms.[36,37]

Anxiety caused by fluctuating plasma concentrations of hormones has been well described, although the mechanism of anxiogenesis is poorly understood. Estrogen exerts multiple complex effects on neurotrophins, cortisol, and neurotransmitter systems.[24] One theory linking estrogen dysregulation to anxiety involves estrogen’s role in effective serotonin use. When plasma estrogen concentrations decline significantly, the associated serotonin dysregulation causes anxiety.[23] Progesterone deficiency and supplementation has been linked with anxiety and irritability in women.[23,24] One potential mechanism involves progesterone’s neuroactive steroid metabolites (e.g., 5-tetrahydroprogesterone, allopregnanolone), which are allosteric modulators of $GABA_A$, causing anxiolytic effects in some and anxiogenic effects in others, depending on an individual’s genetic susceptibility to anxiety and progesterone metabolite formation.[78,87] In addition, progesterone possesses some antiestrogen activity that can precipitate anxiety in some individuals.[23] GnRH agonists are synthetic derivatives of the native decapeptide produced by the hypothalamus, and may cause anxiety via reversible suppression of the synthesis and release of luteinizing and follicle-stimulating hormones which ultimately leads to reduced synthesis of sex hormones (e.g., testosterone).[28] Similarly, GnRH antagonists can be expected to induce anxiety by suppressing gonadotropin hormone release.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms associated with drug-induced anxiety are listed in **Table 19-4**. An individual with significant anxiety experiences a combination of physical, emotional, and cognitive symptoms that may challenge his or her ability to interact with others, think clearly, or participate in the activities of daily living. Table 19-4 differentiates physical, emotional, and cognitive symptoms of anxiety that may be further rated as mild, moderate, or severe, depending on the impact of these symptoms on the individual's ability to function.

Table 19-4 Signs and Symptoms Associated with Drug-Induced Anxiety[1-4,8-16]

Emotional

- Fear of "going crazy"
- Fear of losing control
- Feeling "on edge"
- Feeling jittery
- Feeling of impending doom
- Feelings of inferiority
- Irritability
- Sadness
- Tearfulness

Cognitive

- Blanking out
- Difficulty concentrating
- Extreme worries
- Intrusive thoughts
- Irritability
- Obsessive thoughts
- Rapid or racing thoughts

Physical

- Chest pain
- Choking sensation
- Diarrhea
- Difficulty speaking
- Exaggerated startle response
- Exhaustion
- Fatigue

- Fidgeting
- Flushing
- Hypervigilance
- Insomnia
- Nausea, vomiting
- Palpitations
- Poor eye contact
- Restlessness
- Shaky voice
- Tearfulness
- Tremulousness

Patient assessment should begin by documenting the patient’s experience of anxiety subjectively and objectively. Both clinician-rated (e.g., Hamilton Anxiety Rating Scale) and self-rated standardized anxiety scales (e.g., Beck Anxiety Inventory) are useful to establish objective measures of anxiety and to monitor persistence or remittance of symptoms over time.[4,98] However, these tools are unable to link the symptoms to the cause (e.g., drug-induced anxiety). The clinician’s interview is crucial to investigate whether symptoms are likely drug-induced by establishing the time course of the onset of anxiety in relation to initiation or discontinuation of drug therapy.

An individual’s sensitivity to experiencing caffeine-induced anxiety can vary greatly, but emotional, cognitive, and physical symptoms are all possible. During acute consumption, symptoms of anxiety generally manifest within 15–30 minutes after ingesting between 200 and 500 mg of caffeine or 3–5 cups of brewed coffee or may occur as caffeine withdrawal 1–2 days after abrupt discontinuation.[1,17,18] The onset of anxiety symptoms associated with benzodiazepine withdrawal is related to the half-life of the specific agent. For short- to intermediate-acting agents such as alprazolam or lorazepam, withdrawal symptoms can occur within 6–24 hours of abrupt cessation, whereas withdrawal symptoms can occur within 2–3 days of discontinuing benzodiazepines with longer half-lives, such as clonazepam or diazepam.[13,14] Withdrawal syndromes associated with carisoprodol include symptoms of anxiety, tremors, restlessness, and irritability, among other somatic and neuropsychiatric effects such as headache and insomnia.[63] Restlessness, irritability, tremor, and sweating combined with elevated blood pressure have been reported during pregabalin withdrawal.[7,55] Similar anxiety symptoms accompanied by diaphoresis and palpitations are reported with gabapentin therapy.[27]

It can be difficult to distinguish drug-induced anxiety from other possible causes of anxiety in many patients. Conditions to consider in the differential diagnosis of drug-induced anxiety are listed in **Table 19-5**.[1,4,10,15-17,31,96] A thorough physical examination and medication and substance abuse history are necessary for a comprehensive assessment. Associated symptoms that are more indicative of substance-induced anxiety versus a primary anxiety disorder include new-onset panic attacks after the age of 45 years, vertigo or loss of balance, loss of bladder or bowel control, and slurred speech or amnesia. Also, drug-induced anxiety typically does not meet the duration criteria for a primary anxiety disorder. For example, to meet the criteria for generalized anxiety disorder, anxiety symptoms must cause functional impairment for 6 months.[1,4] In individuals with cancer, distinguishing drug-induced anxiety is particularly difficult because of high levels of situational anxiety related to the diagnosis and the need to endure treatment over months to years.[46]

Table 19-5 Conditions to Consider in the Differential Diagnosis of Drug-Induced Anxiety[1,4,10,15-17,31,96]

- Addison disease
- Akathisia
- Asthma
- Attention-deficit hyperactivity disorder
- Cardiomyopathies
- Chronic obstructive pulmonary disease
- Chronic pain
- Cushing syndrome
- Delirium
- Dementia
- Electrolyte abnormalities
- Fibromyalgia
- Hypertension
- Hyperthyroidism or Graves disease
- Hypoglycemia
- Irritable bowel syndrome
- Mitral valve prolapse
- Multiple sclerosis
- Parkinson disease
- Perimenopause
- Pheochromocytoma
- Premenstrual dysphoric disorder
- Premenstrual syndrome
- Seizure disorder or epilepsy
- Systemic lupus erythematosus
- Traumatic brain injury

Table 19-6 outlines a systematic approach to patient assessment and lists key questions useful in assessing drug-induced anxiety and differentiating it from a primary anxiety disorder.[4,97] Laboratory or other diagnostic tests are useful to determine whether there is an underlying medical cause or associated medical problem such as hyperthyroidism or mitral-valve prolapse and to identify substances potentially involved via urine toxicology tests.

Table 19-6 Clinical Assessment and Differential Diagnosis of Drug-Induced Anxiety[4,88]

Diagnostic interview

1. Record emotional, cognitive and physical symptoms of anxiety.
2. Rate each symptom as mild, moderate or severe using standardized anxiety rating scales (e.g., HAM-A, GAD-7)
3. Document functional impairment from anxiety
4. Conduct medication and substance abuse history

Key questions

"Yes" responses increase likelihood of drug-induced anxiety

1. Does individual have current psychiatric illness?
2. Does individual have a chronic medical illness?
3. Is situational anxiety considered unlikely?
4. Did the onset of anxiety happen within 1 week of the initiation of a substance or an ↑ or ↓ in dose of a substance?

Physical assessment

1. Physical examination
2. Record vital signs
3. Obtain toxicology screen
4. Obtain appropriate laboratory and diagnostic tests (e.g., TFTs if hyperthyroidism, ECG if cardiac symptoms reported)

ECG = electrocardiogram, HAM-A = Hamilton Anxiety Rating Scale, GAD-7 = generalized anxiety disorder 7-item scale, TFT = thyroid-function test.

RISK FACTORS

Risk factors for drug-induced anxiety are listed in **Table 19-7**.[1-4,13,14,24,39,96,97] Clinical studies show that individuals with an existing anxiety disorder or elevated levels of anxiety, particularly panic disorder (PD) or post-traumatic stress disorder (PTSD), are especially sensitive to worsening panic attacks, hypervigilance, and exacerbated anxiety when taking even low doses of drugs known to cause anxiety.[23,38,43,99,100] For example, a controlled trial of the anxiogenic effects of the dopaminergic agonist bromocriptine and the dopaminergic antagonist sulpiride found that stimulation of dopaminergic function may cause anxiety in high-anxiety individuals at baseline and may exert anxiolytic effects in low-anxiety and otherwise healthy individuals.[21] Furthermore, individuals with primary anxiety disorders including social anxiety disorder (SAD), generalized anxiety disorder (GAD), and obsessive–compulsive disorder (OCD) are more susceptible to worsening anxiety associated with well-known anxiogenic substances such as caffeine or stimulants. Patients with a history of PD are more likely to experience panic attacks after use of glucocorticoids, especially in younger adults between the ages of 18 and 30 years.[71] Other psychiatric illnesses, including schizophrenia, schizoaffective disorder, bipolar disorder, and ADHD are associated with higher rates of anxiety and anxiety disorders compared with the nonaffected population. For this reason, drug-induced anxiety is also more common in these patients.[1,2,4] Parkinson disease can be considered a risk factor given the high rates of anxiety in this population and particularly during the off-period where anxiety is significantly more severe.[96]

Table 19-7 Risk Factors for Drug-Induced Anxiety[1-4,13,14,24,37,88,93,108,109]

- Primary anxiety disorder(s)
- Presence of any chronic psychiatric illness (e.g., bipolar disorder, major depression, schizoaffective disorder, schizophrenia)
- Presence of chronic medical condition(s)
- Use of more than one drug(s)/substance(s) known to provoke anxiety
- Currently withdrawing from sedative–hypnotic medication
- Currently withdrawing from alcohol or another substance of abuse
- Elevated plasma concentrations of potentially anxiety-provoking agents
- *ADORA2A2* gene polymorphisms in panic disorder, caffeine and amphetamine users

Multiple genes encoding for proteins or enzymes have been identified that confer risk of developing an anxiety disorder.[99] For example, in PD, polymorphisms in genes encoding monoamine oxidase-A (MAO-A) in females, cholecystokinin receptors, several serotonin receptor subtypes (e.g., 5-HT$_{1A}$), and tryptophan hydroxylase 2 are possible risk factors.[100-103] Serotonin gene polymorphisms (5-HTTLPR), particularly the SS genotype, are probable risk factors for developing PTSD in nonhispanic black veterans and following exposure to combat or genocide trauma.[104-105] The SS genotype may also confer risk of developing social anxiety symptoms.[106]

Despite the growing evidence of candidate genes involved in the psychopathogenesis of anxiety disorders, PTSD, and OCD, the influence of genetic polymorphisms and their phenotypes on exacerbation or development of anxiety symptoms upon exposure to anxiogenic drugs is not well defined. Single nucleotide polymorphisms, rs5751876 (1976 C/T) and rs35320474 (2952 C/Tins), within the ADORA2A genotype may confer risk of anxiety in light caffeine users (<300 mg of caffeine per week).[107] The genetic polymorphism 1976T/T-2592 Tins/Tins may also be a factor that contributes to the heightened anxiety observed after 10–20 mg of amphetamine administration in individuals who are light smokers (<10 cigarettes per week) and moderate caffeine consumers (1–2 cups per day).[107-109] The A2A polymorphism may also be a shared genetic trait in individuals with PD, which could explain the increased sensitivity to caffeine in this population.[18,107]

Risk and intensity of anxiety during nicotine withdrawal is a function of the amount of daily nicotine use and individual sensitivity to withdrawal discomfort. However, nicotine-dependent individuals with a comorbid primary anxiety or mood or substance use disorders are more likely to experience a greater number of withdrawal symptoms and have higher risk of relapse upon cessation attempts.[110,111] Thus, nicotine withdrawal anxiety can occur after abrupt cessation of cigarette smoking but also after abrupt discontinuation of nicotine replacement therapies such as gum, inhalers, lozenges, or, less often, nicotine patches.[33] Combining smoking cessation products to increase chances of sustained abstinence, such as with varenicline and bupropion, also increases the risk of secondary anxiety compared to that associated with varenicline monotherapy.[112]

Individuals who misuse or abuse stimulants or those with narcolepsy taking high doses are the most likely to experience intolerable anxiety symptoms.[5-7] Modafinil and its R-enantiomer, armodafinil, are nonstimulant compounds that are anxiogenic. Although higher doses (e.g., modafinil doses >400 mg) pose a greater risk, individual sensitivity should be considered as anxiogenic effects can occur with lower doses.[32,50] Modafinil 200 mg and armodafinil 150 mg appear to cause anxiety symptoms at comparable rates when used for shift-work sleep disorder.[50] In addition, severe anxiety, restlessness, and palpitations with armodafinil doses of 150 mg or more have required discontinuation in clinical trials when used for a variety of sleep disorders, schizophrenia, and bipolar depression.[51-53]

Drug-induced anxiety is more pronounced at higher drug doses. For example, it is uncommon for patients to experience anxiety associated with pseudoephedrine at doses as low as 30 mg. However, the 120-mg sustained-release dose is associated with a greater risk of anxiety.[35] Anxiety associated with ephedrine, bitter orange (*Cypraea aurantium*, synephrine), caffeine, guarana, yohimbine, and steroids is also dose-related.[7,13,22,33,38,71] In addition, drug-induced anxiety is more likely in patients with impaired hepatic or renal function who are taking potentially causative agents for which the liver or kidney, respectively, contribute substantially to drug clearance.

MORBIDITY AND MORTALITY

There is no direct connection between drug-induced anxiety and increased mortality. However, there is increasing evidence linking anxiety to negative health consequences including heart disease, impaired disease recovery, and increased propensity for poor health habits such as cigarette smoking and abuse of alcohol and other substances.[2,3,113-116] Anxiety disorders may cause altered hypothalamic-pituitary axis responses secondary to imbalances of cortisol and anti-inflammatory and proinflammatory cytokines.[117] For example, tumor necrosis factor-α has been found in higher concentrations in individuals with GAD and PTSD.[117] Imbalances of cortisol have also been associated with PTSD, GAD, and OCD. However, it is unclear if cortisol imbalances contribute to PD, SAD, or to drug-induced anxiety. The impact of these associations on morbidity remain to be elucidated. Although elevations in pro-inflammatory cytokines are recognized as risk factors for cardiovascular morbidity, the impact of drug-induced anxiety on risk of cardiovascular morbidity or death is unknown.

PREVENTION

Approaches to prevention of drug-induced anxiety are listed in **Table 19-8**. Preventing drug-induced anxiety starts with patient assessment to determine whether risk factors are present. If one or more risk factors exist, the clinician should carefully weigh the risk versus the benefits of initiating therapy with a drug known to cause anxiety. Alternative treatments with a lower risk for inducing anxiety should be considered. If the drug in question represents the most appropriate treatment option, initiation of therapy should be gradual, with careful dose titration and monitoring to detect the emergence of anxiety and determine the need for treatment with psychotherapeutic or pharmacologic interventions. If discontinuation of antidepressant therapy is necessary, the dose should be reduced gradually over 2–6 weeks to prevent serotonin withdrawal syndrome (symptoms include worsening anxiety or insomnia).[4,37] If discontinuation of therapy with agents known to cause anxiety upon drug withdrawal is necessary (e.g., benzodiazepine, barbituates), tapering the dose gradually over weeks to months can minimize the risk of anxiety.[4,13] Doses of drugs known to cause anxiety that predominantly undergo renal or hepatic clearance should be reduced appropriately in patients with kidney or liver disease, respectively.

Table 19-8 Approaches to Help Prevent Drug-Induced Anxiety[1-4]

- Assess patient for an underlying anxiety disorder or history of drug-induced anxiety to determine the risk of drug-induced anxiety
- Counsel patient regarding the risk of anxiety when initiating or discontinuing therapy with a potentially causative drug
- Initiate therapy with potentially anxiety-provoking medications slowly, with gradual dose titration. For example, initial doses of selective serotonin reuptake inhibitors can be reduced by half
- Minimize use of multiple medications with a risk for inducing anxiety

MANAGEMENT

Management of drug-induced anxiety is largely supportive and typically involves lowering doses or discontinuation of the causative agent. For example, anxiety symptoms associated with steroid supplementation or hormone replacement typically resolve within 2–4 weeks of cessation of therapy.[24,72] Supportive treatment may include reassurance, instruction on relaxation techniques, and avoidance of other substances known to cause anxiety. Antidepressant-induced anxiety is usually transient during initiation or abrupt discontinuation of therapy. Slower dose titration during initiation of therapy and gradual dose tapering during discontinuation can minimize or alleviate anxiety symptoms and is critical in patients with a history of antidepressant-induced anxiety. Effective management of antipsychotic-induced anxiety involves a dose reduction, substituting therapy with an antipsychotic agent with lower dopaminergic antagonist activity and more histamine antagonism, or treating the anxiety with a β-adrenergic blocker or benzodiazepine when the former is not appropriate.[10,11]

In cases in which therapy with the anxiety-provoking agent cannot be discontinued (e.g., in patients who are undergoing cancer chemotherapy), temporary management with a benzodiazepine can be considered. Lorazepam 0.5–1 mg administered two or three times daily offers the advantage of rapid onset (30–45 minutes), intermediate duration of effect (~6–8 hours), and no active metabolites that can accumulate. Clonazepam 0.25–0.5 mg administered once or twice daily can be considered if less frequent administration is desired, but the onset of effect may be longer (1–2 hours) and the drug can accumulate over time because of a long half-life of 20–50 hours. The duration of supportive therapy varies based on the necessary duration of treatment with the causative agent.[4] Withdrawing therapy slowly and over a longer period of time (over months instead of weeks) may attenuate anxiety related to abrupt benzodiazepine discontinuation. Alternatively, therapy with an agent that increases GABA activity, such as valproic acid, can be initiated to diminish withdrawal symptoms and associated anxiety.[13]

Caffeine-induced anxiety and withdrawal symptoms abate with time (typically 3–7 days) and may be managed with mild analgesics to treat headache symptoms.[6,17,22] There is evidence that exercise attenuates caffeine-induced state anxiety in nonsmoking males.[118] Nicotine supplementation with gradual tapering can lessen anxiety associated with nicotine withdrawal.[23]

The management of anxiety induced by thyroid supplementation includes reducing the dose or discontinuing the thyroid supplement and providing patient counseling and reassurance as necessary.[74] A clinician with expertise in hormone regulation should be consulted when patients present with anxiety related to hormonal imbalance. Management strategies include hormonal supplementation or discontinuation, treatment with antianxiety medication (e.g., SSRIs), or both.

INFORMATION FOR PATIENTS

Individuals prescribed medications known to cause anxiety during treatment or withdrawal and those who elect to take nonprescription drugs known to cause anxiety should be warned of the risks. Patient education regarding the risk of withdrawal symptoms after discontinuation of a CNS-active agent is essential. Individualized discontinuation regimens should be developed based on patient tolerance. For example, decreasing the dose of a benzodiazepine by 25% per week is well tolerated by some patients, but others may require more gradual tapering over weeks or even months.[4,13] Patients who have difficulty withdrawing from benzodiazepine therapy because of excessive anxiety should be offered the option of therapy with anticonvulsant drugs, as these agents have been used effectively to prevent anxiety and other benzodiazepine withdrawal symptoms such as insomnia and tremulousness.[13,14]

When drug-induced anxiety occurs, the caregiver should reassure the patient that drug-induced anxiety is usually of short duration (days to weeks) and will improve after a dose decrease or discontinuation of the causative agent along with supportive treatment. Patients at risk for anxiety should be counseled regarding the type of anxiety symptoms that may occur in association with the drug (e.g., panic attacks, jitteriness, fearful thoughts), the typical time of onset of symptoms, and available interventions should anxiety occur.

CHAPTER 20

Psychosis

Jessica L. Gören

The term *psychosis* was first introduced in the 19th century to describe the manner in which mental illness, manifested as aberrant behavior, related to both psychological and physical well-being. Psychosis is currently defined as an impairment of reality testing due to gross distortion or disorganization of reality.[1-5] Patients with psychosis experience gross inaccuracy of perception, even with evidence to the contrary. Visual, auditory, tactile, and olfactory hallucinations, delusions or fixed false beliefs, and illusions (distortion in perception) often characterize the impaired reality testing associated with psychosis. The associated physical symptoms can include agitation, anxiety, aggression, pacing, unusual behaviors such as talking to someone not visible to others, and withdrawal from society. Although psychosis is a relatively common medical disorder, it is not a specific diagnosis but rather a feature of many disease states.[1-8]

CAUSATIVE AGENTS

Many medications are associated with drug-induced psychosis (**Table 20-1**) and withdrawal psychosis (**Table 20-2**).[9-124] Agents more commonly implicated include amphetamines, anticholinergics, corticosteroids, anabolic steroids, dopaminergic agents, ma huang (ephedrine), and tacrolimus.[2,3,5-8] The pharmacological diversity of these drugs clearly indicates that no single mechanism of action can be fully responsible for drug-induced psychosis. In fact, the mechanisms seem to be as complex and poorly understood as those associated with idiopathic psychosis.

The causes of drug-induced psychosis extend beyond U.S. Food and Drug Administration (FDA)-approved medications to include herbal and nutritional supplements used by many. Several illicit drugs such as lysergic acid diethylamide (LSD), psilocybin, and phencyclidine (PCP) induce psychotic states similar in presentation to psychosis induced by legal medications.[42,125-127] Increasingly, newer synthetic drugs of abuse such as synthetic cathinones (e.g., bath salts) and synthetic cannabinoids (e.g., K2, spice) have been associated with psychosis.[128,129] For all of these agents, drug-induced psychosis may occur at normal doses, excessive doses (intoxication) or, occasionally, as a component of a withdrawal phenomenon. Chronic exposure can also lead to drug-induced psychosis, particularly with synthetic cathinones and cannabinoids.[128,129]

Table 20-1 Agents Implicated in Drug-Induced Psychosis

Drug	Incidence	Level of Evidence[a]
Albuterol[9-11]	NK	C
Amantadine[12,13]	1–10%	C
Amphetamines[14-16]	0.25%[b]	A
Anabolic steroids[17]	12%	B
Angiotensin-converting enzyme inhibitors[18-20]	NK	C
Anticholinergics[21-29]	7%	A
Bupropion[30-32]	NK	C
Caffeine[33,34]	NK	C
Carbamazepine[35-37]	NK	C
Celecoxib[38]	NK	C
Chloroquine[39]	NK	C
Ciprofloxacin[40,41]	NK	C
Cocaine[42]	NK	C
Corticosteroids[43-47]	1%	B[d]
Cyclobenzaprine[48,49]	<1%	C

Cycloserine[50,51]	15%	B
Dapsone[52]	NK	C
Dextromethorphan[53,54]	NK	C
Digoxin[20,55]	NK	C
Diphenhydramine[26,29]	NK	C
Disulfuram[56,57]	NK	C[d]
Dopamine agonists[58-63]	>1%	C
Doxazosin[20]	NK	C
Dronabinol[64,65]	3–10%	C
Efavirenz[66]	1%	C
Ephedrine[67-69]	NK	C
Guanfacine[70,71]	NK	C
Ganciclovir[72]	<1%	C
Histamine$_2$ blockers[73-76]	NK	C
HMG CoA reductase inhibitors[77,78]	NK	C
Ifosfamide[79]	<12%	B
Indomethacin[80,81]	<1%	C
Isoniazide[50]	<1%	C
Lacosamide[82,83]	NK	C
Lidocaine[84]	NK	C
Ketamine[85]	12%	B
Levetiracetam[86,87]	1% adult 2% pediatric	A
Levodopa–carbidopa[58,88]	NK	A
Levothyroxine[89]	NK	C
Mefloquine[90,91]	NK	C
Meperidine[92,93]	NK	C
Methylphenidate[16,94]	0.25%[b]	A
Metoprolol[95,96]	NK	C
Modafinil[97]	NK	C
Monoamine oxidase inhibitors[98-100,c]	NK	C
Nitrous oxide[101,102]	NK	C

Pseudoephedrine[59,103,104]	NK	C
Quinidine[105,106]	<1%	C
Sibutramine[107-109]	NK	C
Tacrolimus[110,111]	<15%	C
Tiagabine[112]	0.8%	B
Trimethoprim–sulfamethoxazole[113,114]	NK	C
Vigabatrin[115,116]	NK	C
Zolpidem[117,118]	1–10%	C
Zonisamide[115,119]	2%	A

HMG CoA = 3-hydroxy-3-methylglutaryl-coenzyme A, NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Therapeutic doses of prescription amphetamines and methylphenidate.

[c] Varies by agent.

[d] Most commonly in association with mania.

Table 20-2 Drugs Implicated in Withdrawal Psychosis

Drug	Incidence	Level of Evidence[a]
Alcohol[120]	5%	B
Benzodiazepines[121,122]	NK	B
Opiates–opioids[123,124]	NK	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

EPIDEMIOLOGY

In the 19th century, Jacques-Joseph Moreau de Tours was the first psychiatrist to describe drug-induced psychosis.[2] Despite such a long period of awareness of the problem, the incidence of drug-induced psychosis is still unknown. Limited data exist regarding the incidence of drug-induced psychosis associated with specific medications or conditions. In addition, drug-induced psychosis often occurs more commonly in patients with certain diseases and when drugs are abused chronically or in high doses. The incidence of psychosis in methamphetamine users was reported to be 11 times greater than that of the general population, with 23% of users reporting at least one psychotic symptom in the past year.[130] In an FDA meta-analysis, therapeutic doses of stimulants caused psychosis in one in 400 children.[14] Up to 21% of patients with Parkinson disease receiving a dopamine agonist experience psychotic symptoms, while fewer than 1% of patients with bipolar disorder exhibit similar symptoms.[58] Predisposing factors such as very young or older age groups, psychiatric and neurologic illnesses, and polypharmacy are known to increase the incidence of drug-induced psychosis.

MECHANISMS

Psychosis is not a single disorder, but rather a symptom induced by multiple mechanisms. **Table 20-3** lists some drugs and their mechanism for inducing psychosis. The precise pathophysiology of idiopathic psychosis is not well understood and even less is known about drug-induced psychosis. Overlap in clinical presentation of idiopathic psychosis and psychosis caused by both legal and illicit drugs suggests similar mechanisms. Understanding of drug-induced psychosis, therefore, may be enhanced by a discussion of the pathophysiology of idiopathic psychosis and the psychosis associated with illicit drug use.

Table 20-3 Mechanisms of Drug-Induced Psychosis[2,3,5-8,125-127,131-137]

Drug(s)	Mechanism(s)
Amantadine Apomorphine Bromocriptine Levodopa Pramipexole Ropinirole Rotigotine	Increased dopamine concentrations in CNS
Albuterol Disulfiram Dronabinol Ephedrine Ketamine Nitrous oxide	Increased norepinephrine concentrations
Amphetamine Bupropion Cyclobenzaprine Monoamine oxidase inhibitors	Increased dopamine concentrations in CNS Increased norepinephrine concentrations in CNS

Methylphenidate Pseudoephedrine Sibutramine	
Dextromethorphan Ketamine Phencyclidine	Glutamate NMDA receptor antagonist
Anabolic steroids	Down regulation of serotonin 1B receptor density in the hippocampus and globus pallidus Up regulation of serotonin 2 receptor density in the nucleus accumbens
Anticholinergics	Decreased cholinergic function
Anticonvulsants Zolpidem	Enhanced GABAergic effects
Chloroquine Fluoroquinolones	NMDA agonist GABA antagonist
Cycloserine	NMDA partial agonist
HMG CoA reductase inhibitors	Decreased brain cell membrane cholesterol leading to decreased serotonin receptors and altered serotonergic functioning

CNS = central nervous system, GABA = gamma-aminobutyric acid, HMG CoA = 3-hydroxy-3-methylglutaryl-coenzyme A, NMDA = *N*-methyl-D-aspartate.

Psychosis is often associated with alterations of dopamine concentrations in various regions of the brain.[2,6] Increased dopaminergic function in the mesolimbic pathway is associated with hallucinations, delusions, and paranoia.[2,5-8] Increased release of dopamine and/or decreased metabolism or uptake of dopamine can cause psychotic symptoms. This is supported by the observation that administration of mesolimbic dopamine antagonists leads to clinical improvement of psychotic symptoms.[6] Although a hyperdopaminergic state is an important mechanism of both idiopathic and iatrogenic psychotic states, studies indicate it is only one mechanism involved in the provocation of psychotic symptoms.[2,5-8]

Other neurotransmitters may indirectly alter synaptic concentrations of dopamine leading to psychosis. Glutamate, serotonin, norepinephrine, and acetylcholine are believed to exert secondary affects on dopamine neurotransmission and to play a role in psychosis.[2,5-8]

Altered serotonin [5-hydroxytryptamine (5-HT)] receptor functioning is also associated with psychosis. Patients with schizophrenia have abnormal 5-HT receptor functioning, and many antipsychotic agents exert significant effects on serotonergic functioning.[6,131-136] LSD, an agent known to induce hallucinations, is structurally related to serotonin. LSD and psilocybin induce psychosis through stimulation of the 5-HT$_{2A}$ receptor.[126,127]

Glutamate is the major excitatory neurotransmitter in the brain.[5-7] Antagonism of the glutamate *N*-methyl-D-aspartate (NMDA) receptor by PCP and ketamine induces states that may be the best model of idiopathic psychosis.[137,138] Biologic changes associated with hypoglutamatergic function in schizophrenia include decreased glutamate in the cerebrospinal fluid, altered NMDA receptor densities, and decreased glutamate release.[139-141]

It has been hypothesized that altered intracellular signal transduction may be involved in psychosis.[142,143] Gene induction associated with antipsychotics leads to increased expression of the oncogene c-fos or its protein product, which may alter expression of other genes, the products of which are involved directly in psychosis. Another mechanism posited to play a role in psychosis is episodic dysfunction of myelin sheaths disrupting subcortical and cortical processes, which may lead to positive psychotic symptoms and cognitive dysfunction.[142,143]

Alteration of dopamine and serotonin are consistently associated with psychosis. However, the biologic mechanism of psychosis is complex, involves multiple pathways, and has not been fully elucidated. Therefore, the ability to predict drugs that are less likely to induce psychosis based on pharmacological activity is limited at this time.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Many symptoms in patients with drug-induced psychosis are similar to those of patients with idiopathic psychoses such as schizophrenia, which is defined by a triad of symptoms: positive, negative, and cognitive.[2-4,8,144] Positive symptoms include delusions, hallucinations, and disorganized speech and behavior.[2-8] Negative symptoms include flat affect, avolition, and social isolation.[2-8] Cognitive symptoms can be diverse but often present as difficulties with concentration and memory.[7,8] Positive symptoms are more typically associated with drug-induced psychosis than negative symptoms (**Table 20-4**).

Table 20-4 Symptoms Associated with Drug-Induced Psychosis[2-8,144]

Symptom	Examples
Auditory hallucinations	Hearing voices
Visual hallucinations	Seeing thing that are not there
Tactile hallucinations	Feeling bugs crawling on skin
Paranoia	Feelings of persecution
Thought removal/insertion/broadcasting	Feeling that thoughts are being withdrawn, inserted or broadcasted

Thought blocking	Sudden derailment of speech
Ideas of reference	Feeling that there are hidden messages or special meaning in things unrelated to oneself
Grandiosity	Feeling overly self important
Disorganized speech/behavior	Tangential Illogical Perseveration
Anxiety	Pacing, excessive worry
Agitation	State of extreme anxiety
Delusions	Fixed false beliefs

There is no individual test that is diagnostic for drug-induced psychosis. Diagnosis depends on identification of a temporal relationship between the ingestion of the potentially causative substance and the onset of psychotic symptoms, clinical presentation, medical history and a thorough medication history.[4,8,144] Patients who are acutely psychotic may or may not be able to provide an accurate history. Consultation with family, friends, and other healthcare providers is useful in understanding any pre-existing mental health issues and recent changes in behavior or medical treatment.

A thorough medication history is crucial to the differential diagnosis of drug-induced psychosis. A clear understanding of a patient's baseline psychiatric state and the medications used to treat the disorder may help clinicians distinguish between an underlying disorder that is worsening and a drug-induced psychosis.[2-8,144] **Table 20-5** lists conditions that should be ruled out prior to the diagnosis of drug-induced psychosis.

Table 20-5 Conditions to Consider in the Differential Diagnosis of Drug-Induced Psychosis[2-8,144]

- Infection (including HIV)
- Metabolic abnormalities
- Liver disease
- Hyperthyroidism
- Substance abuse
- Seizure disorder
- Parkinson disease
- Huntington disease
- Tumor/lesions
- Stroke
- Autoimmune disorders
- Alzheimer disease

HIV = human immunodeficiency virus.

The medication history should include use of prescription, nonprescription, and illicit drugs and should document any herbal or nutritional supplements being taken. Although drug-induced psychosis is often associated with recent changes in medication therapy (hours to days), the onset may occur much later in treatment with some agents, such as corticosteroids.[43-47] Also, recent discontinuation of medications should be documented, because drug withdrawal can be accompanied by psychotic symptoms.[120-124] Additionally, recent changes in nonpsychotomimetic medications can play a role in drug-induced psychosis. For example, a nonpsychotomimetic drug could antagonize the psychotomimetic effects of another agent or induce its metabolism.[2,6,8] When questions exist about the veracity of a patient's response to queries regarding substance abuse, urine and blood toxicology screening should be performed. **Table 20-6** lists common drugs of abuse and duration of detection in the urine following the last dose.[145]

Table 20-6 Duration of Detection of Drugs in Urine[145]

Drug	Duration of Detection
Alcohol	12 hours
Amphetamine	Up to 2 days
Opioids	Up to 4 days
Benzodiazepines	1 day to weeks[a]
Barbiturates	1 day to 3 weeks
Cocaine metabolites	2–4 days
Marijuana	1 day to weeks[a]

[a] Depends on quantity and frequency of use.

The psychotomimetic effects of many medications are dose-related.[8,29,31,34,49,52,56,57,89,144] However, interpatient variability exists in the dose at which a medication can cause psychotic symptoms. The recent initiation of therapy with a new psychotomimetic medication or a dose increase in current therapy should always be considered as possible causes when a patient experiences a new onset of psychotic symptoms.

Laboratory monitoring can be helpful to rule out alternate causes of psychosis.[2,3,5,7,8,144] **Table 20-7** provides a list of laboratory tests useful in the differential diagnosis of psychosis. In many cases, the decision to perform laboratory monitoring is based on history and clinical presentation.

Table 20-7 Tests to Aid in the Differential Diagnosis of Drug-

Induced Psychosis[3,5,7,8,144]

Standard laboratory monitoring

- Complete blood cell count with differential
- Electrolytes
- Liver function
- Thyroid function
- Toxicology screen

Monitoring if clinically indicated by patient history

- HIV
- Antinuclear antibodies
- Sedimentation rate
- EEG
- Head CT/MRI

CT = computed tomography, EEG = electroencephalogram, HIV = human immunodeficiency virus, MRI = magnetic resonance imaging.

Diagnosis of drug-induced psychosis is a diagnosis of exclusion.[2,3,5,7,8,144] The integral components of diagnosis are accurate medication, medical, psychiatric, and physical histories, physical examination, and laboratory monitoring.[2,3,5,7,8,144] In many instances, a thorough history is sufficient to diagnose drug-induced psychosis.

The *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition*, includes several diagnoses that encompass drug-induced psychosis (termed *substance/medication induced*), including substance/medication-induced psychosis and substance/medication-induced bipolar and related disorders. A key criterion of substance-induced psychosis is absence of delirium.[4] Delirium is differentiated from psychosis by its fluctuating course, disturbances of consciousness, and changes in cognitive processes such as memory.[4] Although these problems may occur in drug-induced psychosis, they are more often indicative of delirium. Research demonstrates that the clinical diagnosis of drug-induced psychosis remains accurate in greater than 70% of cases at 24 months, indicating standard interview, history gathering, and routine laboratory monitoring are sufficient for an accurate diagnosis in most cases.[146]

Prominent hallucinations or delusions are typically present in patients with drug-induced psychosis.[2,3,8,144] Often hallucinations are visual, tactile, and gustatory, whereas auditory hallucinations predominate in idiopathic psychotic disorders.[2,3,8,144] Patients who have insight into psychiatric symptoms that are drug-induced do not meet the criteria for a substance/medication-induced psychosis and should be diagnosed as substance intoxication or withdrawal with perceptual disturbances.[4] However, patient insight is a controversial diagnostic exclusion, as many patients who have insight into their symptoms nonetheless require treatment for psychotic symptoms.[144]

Onset of illness must be assessed to accurately diagnose drug-induced psychosis. Idiopathic psychotic disorders tend to occur during specific periods in life and have a slow progressive and degenerative course.[2,3,5-8,144] Abrupt onset or atypical presentations such as a late age of onset may indicate drug-induced psychosis, which is usually associated with recent medication changes and occurs within hours to days of the change.[2,3,5-8,144] In some rare cases the onset may be more protracted, as is the case with corticosteroid-associated psychosis, which may occur as late as 3 months after medication changes.[43-47]

Duration of symptoms may also help clarify the diagnosis. When symptoms do not remit within 4 weeks after discontinuation of the potentially causative agent, other causes of psychosis must be considered.[4,8,144] Protracted psychosis is not common when the disorder is drug-induced.

Physical symptoms may differ between drug-induced psychosis, intoxication, and idiopathic psychotic states. Typically, drug-induced psychosis is not associated with gross physical abnormalities.[4,8,144] Slurred speech or ataxia are more commonly associated with intoxication and delirium rather than idiopathic or drug-induced psychosis.[2,3,5-7,8,144] Intoxication, drug withdrawal, or delirium are often associated with physical characteristics such as changes in pupil size, tachycardia, sweating, pain and cramping, altered gastrointestinal motility, and drug cravings that are often not present in patients with drug-induced psychosis.[4,5,7,8,144]

Some drugs are associated with a pattern of signs and symptoms that may help identify them as causative agents. Stimulant-induced psychosis is often associated with mydriasis, tachycardia, arrhythmias, and brisk reflexes.[2,3,5-8,14-16] Benzodiazepine withdrawal is associated with tremors, fever, and seizures.[2,3,5-8,121,122,144] Mydriasis, tachycardia, urinary retention, and constipation accompany anticholinergic-induced psychosis.[2,3,5-8,24,144] Although anticholinergic-induced psychosis occurs more commonly in association with oral or parenteral administration, it has also been reported with transdermal use.[27]

RISK FACTORS

Specific risk factors for drug-induced psychosis are listed in **Table 20-8**. Older age, underlying bipolar or psychotic disorder, compromised kidney or liver function, polypharmacy, concomitant use of multiple psychoactive drugs, and metabolic abnormalities (e.g., electrolyte abnormalities) all increase the risk of drug-induced psychosis. Post-traumatic head injury can cause organic psychosis as well as predispose a patient to drug-induced psychosis.[144,147,148] As the number of risk factors increases, so does the likelihood of drug-induced psychosis.

Table 20-8 Risk Factors for Drug-Induced Psychosis[2,3,5-8,144,147-149]

- Age >40 years
- Infants and children
- Altered liver or kidney function
- Substance abuse
- Concomitant medications
  - Increased burden of medications with additive effects such as anticholinergic agents
  - Drug interactions (including withdrawal of medications)
- Underlying disease states
  - Systemic lupus erythematosus
  - Parkinson disease
  - Psychiatric illnesses
  - HIV
- Head injury

HIV = human immunodeficiency virus.

Patient populations in need of special attention are the elderly, infants and children, and patients with concomitant illnesses. Weight- and age-based dosing are important to decrease risk of drug-induced psychosis for the elderly and children. Prescribing information for individual drugs provides recommendations for dose adjustments for patients with concomitant illnesses such as liver and kidney disease.

In people of any age, concurrent administration of multiple drugs may affect both pharmacokinetic and pharmacodynamic properties of drugs.[5,7,149-153] Increased anticholinergic burden from multiple medications or taking more than nine medications daily substantially increases the risk of drug-induced psychosis.[2,5,7]

Drug interactions that enhance the pharmacological effects and/or increase serum concentrations of potentially causative agents increase the risk of drug-induced psychosis. Pharmacodynamic interactions occur when two medications with similar pharmacological effects have additive or synergistic effects. For example, stimulants and bupropion both increase dopamine and norepinephrine concentrations in the brain. The addition of a stimulant to bupropion treatment could lead to psychotic symptoms that were not present with bupropion monotherapy.

Another potential pharmacodynamic interaction could result from the combination of two drugs that antagonize one other.[154] For example, when a dopamine antagonist is used to treat psychosis, addition of a dopamine agonist can result in the return of psychotic symptoms. Although one would not expect a particularly robust change in dopaminergic antagonism, other pharmacological effects such as anticholinergic transmission could be enhanced leading to increased side effects.

Medications commonly associated with pharmacokinetic drug interactions include antibiotics (ketoconazole, erythromycin), psychotropics (fluvoxamine, fluoxetine, nefazodone), and others (cimetidine, quinidine, protease inhibitors).[149,150,152] Addition of a cytochrome P-450 inhibitor may lead to diminished metabolism of a drug, increased plasma concentrations, and potential for adverse effects.[152,153] Alternately, discontinuation of an agent that was inducing the metabolism of a drug could lead to decreased drug metabolism, increased plasma concentrations, and increased adverse effects, including psychosis.[150] Some agents vulnerable to drug interactions and resulting drug-induced psychosis include stimulants, steroids, opiates/opioids, anticholinergics, antibiotics, β-blockers, angiotensin converting enzyme inhibitors, dopaminergic agents, and antiepileptic medications.[2,3,5,20,149,150,152]

Diligent assessment of medication profiles can help clinicians identify and prevent or treat drug-induced psychosis attributable to drug interactions. Familiarity with those drugs commonly implicated in such drug interactions can help avoid adverse consequences.

MORBIDITY AND MORTALITY

Drug-induced psychosis often requires medical attention to protect the safety of the patient or those around them, although harm due directly to the psychotic state is not typical. Death is rarely directly related to psychosis.[2,3] Death associated with a drug that is causing psychosis is most often the result of a severe intoxication (as may occur with stimulants) or drug withdrawal (as may occur with benzodiazepines).[2-5,121,122]

There is limited information available on the utilization of emergency departments and hospitalizations associated with drug-induced psychosis. One study estimated that 1% of all emergency department visits were related to psychosis.[155] However, the authors did not differentiate between idiopathic and drug-induced psychosis.

Psychosis impairs judgment and insight, which can cause a person to make poor decisions and/or engage in risky behaviors resulting in poor outcomes such as motor vehicle accidents, suicide, or assault.[2,3,8,144] During a psychotic state, patients may misinterpret surrounding events or participate in illegal activities that could lead to incarceration.[2,3,8,144]

PREVENTION

Drug-induced psychosis may be prevented by minimizing risk factors (**Table 20-9**). A thorough history of past and current psychiatric and medical illnesses should be completed. Awareness of all prescription and nonprescription medications and herbal and nutritional supplements is essential to accurately assess risk. Direct inquiry regarding the use of herbal and nutritional supplements is necessary because patients often do not volunteer this information spontaneously.[156,157] Nonpejorative inquiry into illicit drug use and alcohol consumption is important.

Table 20-9 Approaches to Help Prevent Drug-Induced Psychosis

- Utilize lowest dose possible
- Minimize number of concomitant potentially causative medications
- Limit medications with anticholinergic properties
- Adjust doses for elderly
- Avoid use of multiple psychotomimetic medications
- Complete a thorough medication history including nonprescription medications, herbals, alcohol, and illicit drugs

Using the lowest effective doses, age- and weight-appropriate dose selection, avoidance of polypharmacy, and awareness of drug interactions can reduce the risk of drug-induced psychosis. Additionally, in populations with impaired liver or kidney function, aggressive monitoring may help prevent drug-induced psychosis.

No specific monitoring parameters exist for drug-induced psychosis. However, educating the patients, their families, and caregivers regarding the signs and symptoms of drug-induced psychosis may facilitate early identification and treatment.

MANAGEMENT

Drug-induced psychosis is generally self-limiting following discontinuation of therapy with the offending agent. Resolution of symptoms occurs quickly (hours to days) in most patients.[5,7,8,144] Knowledge of the causative medication's half-life provides guidance regarding the likely time frame for symptom resolution. Treatment should include discontinuation of the offending agent, except when it is determined to be medically necessary and no alternate treatments exist. In those situations, decreasing the dose to below psychotomimetic levels and/or treatment of the psychosis with antipsychotic medications may be appropriate. In some cases, the offending agent may be temporarily discontinued and then reinitiated at a lower dose after resolution of psychosis. The dose may then be carefully increased as appropriate for the clinical situation.

Some patients may be detained against their will for observation and medicated if the risk of harm to themselves or others is deemed unacceptable in a court of law.

Some states allow for administration of medication without a court order in emergent situations. Duration of confinement is based on presentation and state law, and therefore treatment options differ from state to state.

Keeping the patient in a safe environment is an important component of treatment during acute psychosis. A safe environment is typically one in which the patient can be observed in a contained location if necessary. Several hours in an emergency department is often sufficient for resolution of symptoms. Drug treatment is rarely necessary following discontinuation of the offending agent.

Medical management is needed if the patient is clearly dangerous to her- or himself or others. In an acute psychotic state, dangerous behaviors may include suicidal or homicidal ideation, violence, extreme paranoia, or unpredictable behaviors. Patients who may hurt themselves or others or may put themselves in dangerous situations typically require acute hospitalization. The goal of acute treatment is to calm the patient and maintain safety. Short-term use of antipsychotics or benzodiazepines may be warranted, provided they are used only during the period of psychosis. Long-term use of these medications places patients at unnecessary risk for complications such as tardive dyskinesia or weight gain and associated metabolic abnormalities. Oral drug administration is preferred; however, in some cases, parenteral administration may be required. Hydration to decrease the risk of delirium is also necessary. Indications of the need for medical management include an inability to maintain a patient's safe behaviors with nondrug measures such as a calm environment, close observation, containment in a limited area or room, or supportive contact with medical professionals, family, or friends.

The choice of medication should be based on efficacy, patient acceptability, and adverse effect profile. The anxiolytic and sedative effects of benzodiazepines render them useful for the treatment of acute agitation and anxiety. Should a patient be disinhibited or become disinhibited with benzodiazepine use, antipsychotics are the drugs of choice. An anticholinergic agent is often administered concomitantly with any antipsychotic agent likely to cause acute extrapyramidal reactions. In patients who are overtly hostile, violent, or aggressive, a combination of benzodiazepines and antipsychotics may be useful.

In cases where withdrawal from a medication is the cause of the psychosis, supportive care is the treatment of choice. Monitoring of subjective complaints and vital signs is useful for identification of patients experiencing withdrawal syndromes. If the discontinuation syndrome places the patient at risk of death or injury, therapy with medication may be reinstituted and the dose then slowly tapered downward for the patient's safety. In the case of benzodiazepines, conversion to a longer-acting agent before downward titration may improve the tolerability of medication discontinuation.[158] However, this is controversial and tapering the original drug can be appropriate treatment.

In instances where discontinuing the offending agent is undesirable (i.e., anti-Parkinsonian agents, corticosteroids), lowering the dose may be sufficient to resolve psychotic symptoms. In cases where drug-induced psychosis is unavoidable to successfully treat the underlying illness, long-term antipsychotic therapy is warranted. In patients with Parkinson disease and drug-induced psychosis, low doses of quetiapine or clozapine are treatments of choice to avoid exacerbation of the underlying movement disorder. Due to adverse effects and associated monitoring procedures required during clozapine therapy, quetiapine is typically viewed as preferred management.[159,160]

In patients with a history of drug-induced psychosis, a rechallenge of the drug may be clinically appropriate. Ideal candidates are patients for whom drug-induced psychosis was the result of high drug doses or concomitant use of multiple psychomimetic medications. Patients who experience psychotic symptoms at low drug doses should not typically be rechallenged. If rechallenge is considered, discussion of the potential risks and benefits of therapy with the patient is important. The drug should be reintroduced at a low dose and with careful monitoring for early signs of psychosis (mild paranoia, agitation, irritability, behavioral changes). Dose increases should be performed over extended time intervals and in smaller increments than usual. In any case, the dose of the agent that is reintroduced should be maintained below previous psychotomimetic doses.

Antidotes are available for several drugs known to cause psychosis (**Table 20-10**). These antidotes are usually necessary only in cases of overdose.[5,154,161-163] Discontinuation of the causative medication and supportive care are often sufficient.[8,144] In cases where an antidote is used, close monitoring to avoid induction of a withdrawal psychosis is necessary.[158,163,164] Specific withdrawal psychosis protocols are limited but are outlined in **Table 20-11**.

Table 20-10 Specific Antidotes for Drug-Induced Psychosis[154,158,161-163]

Anticholinergics

- Physostigmine 0.5–2 mg IM/IV/sub-Q to start, repeating every 20 minutes until response or adverse drug reaction

Opioids

- Naloxone 0.1–0.2 mg IV every 2–3 minutes and repeat every 20–60 minutes

Benzodiazepines

- Flumazenil 0.01 mg/kg over 15 seconds (max 0.2 mg); repeat with 0.005–0.01 mg/kg as needed; do not exceed 3 mg

IM = intramuscular, IV = intravenous, sub-Q = subcutaneous.

Table 20-11 Drug Withdrawal Treatment Protocols[158,164]

Substance	Treatment
Alcohol/benzodiazepine	Chlordiazepoxide 25–50 mg orally every 2 hours as needed for signs/symptoms of withdrawal Supportive care
Opiates/opioids	Methadone 10–20 mg orally every 12 hours; taper over 5–10 days Supportive care

INFORMATION FOR PATIENTS

Patients and their caregivers should be alerted to the potential risks and signs of psychosis whenever psychotomimetic drugs are prescribed. The extent of counseling should be dependent on several factors, including the number of risk factors present, number and severity of comorbidities, polypharmacy, and the dose and number of psychotomimetic medications to be used. Patients and/or caregivers should be instructed to contact their clinician if paranoia, agitation or hallucinations occur.

Patients should be instructed not to take nonprescription medications without first consulting a clinician. Some nonprescription agents associated with psychotomimetic properties include pseudoephedrine, ma huang (ephedra), diphenhydramine, dextromethorphan, and caffeine.[26,29,33,34,53,54,67-69,103] The combination of pseudoephedrine and dextromethorphan in particular increases the risk of psychosis.[103] In addition, patients should be instructed to avoid excessive consumption of caffeinated products.[34,144] Education concerning foods and beverages that are high in caffeine may be necessary depending on the medical sophistication of the patient.

Drug-induced psychosis is often a preventable iatrogenic disease. Careful inquiry about all medications being taken, including nonprescription drugs, complimentary therapies and illicit substances should be completed before making recommendations for nonprescription or prescription drugs. Careful attention should be paid to the combination of agents with high propensity for drug interactions.

Although the outcome of drug-induced psychosis is often favorable, it is important to adequately assess all patients for their risk. Appropriate drug doses, disease and drug monitoring, and minimization of risk factors can improve patient outcomes. Individualization of patient assessments is important because multiple risk factors may substantially increase the risk.

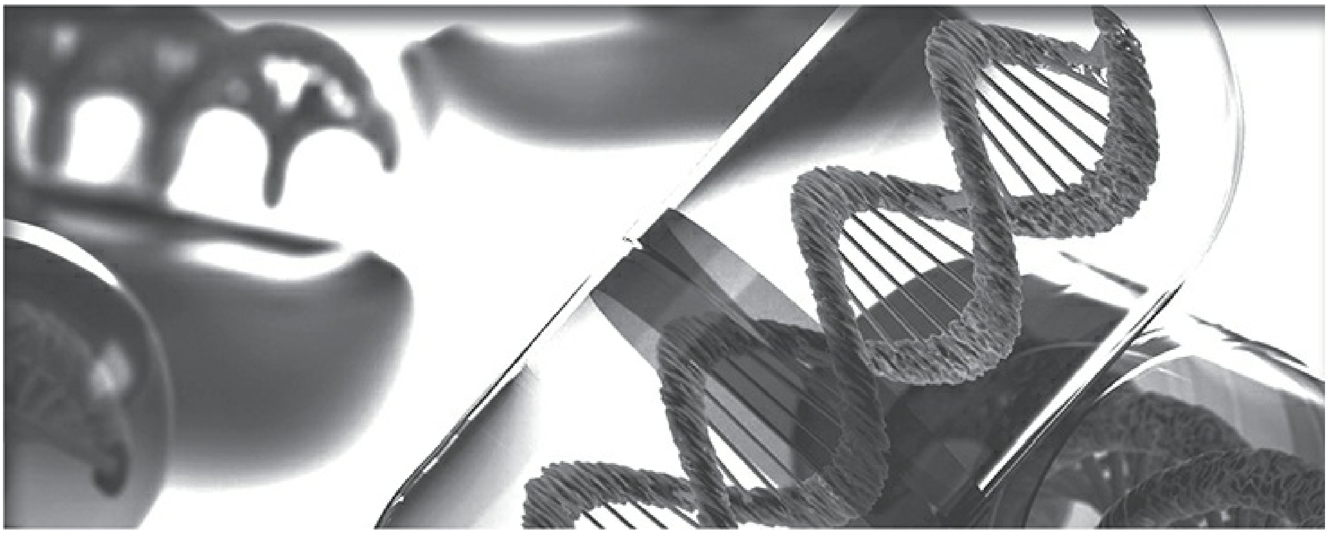
DRUG-INDUCED PULMONARY DISEASES

CHAPTER 21 Interstitial Lung Disease/Pulmonary Fibrosis

CHAPTER 22 Asthma and Bronchospasm



CHAPTER 21

Interstitial Lung Disease/Pulmonary Fibrosis

Jordan R. Covvey and Erin E. Mancl

Interstitial lung disease (ILD) is a collection of more than 300 related lung disorders with diverse pathophysiology that result in progressive thickening/scarring of the tissue surrounding the alveolar sacs. ILD is broadly split into those disorders with known etiology (approximately 35% of cases), and those of idiopathic origin (65%).[1] Drug-induced ILD falls within the former category as an identifiable cause, alongside environmental exposures, autoimmune diseases, cancer, and certain infections. ILD can exist both acutely and/or subacutely as pneumonitis, or may progress over time to chronic pulmonary fibrosis, which is generally irreversible. Although they are separate entities by classification, drug-induced ILD demonstrates some clinical overlap with the most common form of idiopathic ILD, idiopathic pulmonary fibrosis (IPF). In 2014, the U.S. Food and Drug Administration (FDA) approved the first two therapies specifically indicated for the treatment of IPF, ushering in a hopeful era for the treatment for ILD. This chapter will discuss pertinent aspects of drug-induced ILD, with additional discussion of IPF where appropriate.

CAUSATIVE AGENTS

A wide array of drugs have been identified as causing pulmonary toxicity of several types, such as edema, hemorrhaging, pleural disorders, and vasculopathies. For quick reference, an updated online database of drug-induced and iatrogenic causes of pulmonary toxicity can be found at http://www.pneumotox.com, which currently includes over 1,100 identified agents and 23,000 references.[2] Drugs can be searched by name and are listed by the pattern of drug-induced pulmonary toxicity reported in the literature (covering 20 types and hundreds of subclassifications) as well as notation of how many cases have been reported (<10, 10–50, 50–100, 100–200 or >200 cases). Therapies identified as potential causes of drug-induced ILD populate a large list and encompass a number of different mechanisms and chemical structures (**Table 21-1**).[3-298] The most common therapeutic category associated with drug-induced ILD is cytotoxic (chemotherapeutic) agents, including bleomycin, busulfan, and cyclophosphamide, among others. Because many cancer chemotherapy regimens utilize combination therapies, in some cases, pinpointing the causative agent is difficult. For instance, both FOLFOX (folinic acid, fluorouracil, and oxaliplatin) and FOLFIRI (folinic acid, fluorouracil, and irinotecan) regimens for colorectal cancer have been associated with drug-induced ILD, but the precise pharmacological cause in these cases is unclear.[299] Beyond cancer chemotherapy drugs, causative agents include many others, including cardiovascular drugs, anti-inflammatory agents, antimicrobials, biologics, and miscellaneous therapies.[300] Notably, several newer molecularly targeted class-wide effects of interest pertaining to drug-induced ILD have emerged recently, including tumor necrosis factor alpha (TNFα) inhibitors and epidermal growth factor receptor (EGFR) inhibitors. There are limited data associating nonprescription drugs and herbal supplements with drug-induced ILD. However, there are reports linking illicit drugs such as cocaine and heroin with ILD, but the association is somewhat tenuous, and therefore, they are not included in this chapter.[2]

Table 21-1 Agents Implicated in Drug-Induced Interstitial Lung Disease/Pulmonary Fibrosis

Drug	Incidence	Level of Evidence[a]
Amiodarone[3-19]	1–15%	A
Anagrelide[20-22]	NK	C
Antiandrogens[23]		
Bicalutamide[24-28]	NK	C
	NK	C

Flutamide[29-30] Nilutamide[31-33]	NK	C
Aurothiopropanosulfonate (gold salt)[34-36]	NK	C
Azacitidine[37-40]	NK	C
Bepridil[41-44]	3.6%	B
Bleomycin[45-53]	3–40%	A
Bromocriptine[54-61]	1–5.7%	B
Busulfan[62-77]	3–29%	B
Chlorambucil[78-86]	NK	C
Cyclophosphamide[87-97]	1%	B
EGFR inhibitors		
Cetuximab[98-102]	1–1.7%	A
Erlotinib[103-107]	0.4–1%	B
Gefitinib[107-109]	0.3–4%	A
Panitumumab[110-112]	1–1.3%	A
Vandetanib[113]	NK	C
Gemcitabine[114-121]	0.6–7.6%	B
HMG-CoA reductase inhibitors[122-124]	NK	C
Hydroxyurea[125-127]	NK	C
Interferon[128-131]	NK	B
Lenalidomide[132-134]	NK	B
Melphalan[135-140]	NK	C
Methotrexate[141-158]	1–7%	A
Methysergide[159-164]	NK	C
Mitomycin C[165-172]	5–17.6%	B
mTOR inhibitors		
Everolimus[173-175]	13.5%–23%	A
Temsirolimus[176-179]	2–29%	A
Mycophenolate mofetil[180-182]	NK	C
Nitrofurantoin[183-211]	0.02%	B
Nitrosoureas		
Carmustine (BCNU)[212-228]	10–30%	B

Lomustine (CCNU)[229-234]	NK	C
Oxaliplatin[235,236]	NK	C
Pemetrexed[237,238]	NK	C
Penicillamine[239-245]	3%	B
Procarbazine[246-248]	NK	C
Rituximab[249-251]	3.7–10%	B
Sirolimus[252-254]	5–16.7%	B
Sulfasalazine[255-263]	NK	C
Taxanes		
Docetaxel[264-266]	1–5.3%	A
Paclitaxel[267,268]	0–6%	B
TK inhibitors		
Imatinib[269-278]	NK	C
Sorafenib[279-281]	NK	C
Sunitinib[282-284]	NK	C
TNFα inhibitors[155,285-287]		
Adalimumab[288-291]	NK	B
Etanercept[292-296]	NK	B
Infliximab[297,298]	NK	B

BCNU = bis-chloroethylnitrosourea, CCNU = 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea, EGFR = epidermal growth factor receptor, HMG-CoA = 3-hydroxy-3-methylglutaryl-coenzyme A, mTOR = mammalian target of rapamycin, NK = not known, TK = tyrosine kinase, TNFα = tumor necrosis factor alpha.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

EPIDEMIOLOGY

Estimates of the incidence and prevalence of drug-induced ILD are limited due to the rare nature of the disease and the fact that the diagnosis is one of exclusion. Identification of a single therapeutic agent as a definitive cause is difficult in concert with other confounding factors, such as comorbid disease states and therapies, which may compound risk such as immunosuppressive agents and/or radiation therapy. For instance, in one systematic review of ILD among patients with rheumatoid arthritis, over 40% of patients had disease-related ILD prior to exacerbation that was subsequently attributed to TNFα therapy.[155] Therefore, the actual incidence of drug-induced ILD may be greatly underestimated. An important registry of patients with ILD established in New Mexico estimated the incidence and prevalence of drug/radiation-induced ILD to be 1.1–1.8 per 100,000 annually and 1.2–2.2 per 100,000, respectively.[301] ILD associated with drugs or radiation accounted for 2–3% of ILD cases overall, which is the most commonly cited estimate for drug-induced ILD.[301] A more recent epidemiological study using the United Kingdom (UK)-based General Practice Research Database identified an incidence of drug and radiation-induced ILD of 4.1 per 1,000,000 person-years (95% CI 3.4–4.9) from 1997–2008, with only 17% of included cases resulting from drug therapy (the remainder from radiation).[302] IPF is one of the most common forms of ILD.[303] The prevalence of IPF in the United States has been estimated from 4 to 27.9 per 100,000 to as high as 42.7 to 63 per 100,000, depending on the specificity of case definitions.[304] Similarly, incidence estimates were reported at 6.8–8.8 per 100,000 using narrow diagnostic criteria and 16.3–17.4 per 100,000 with broader criteria.[304] Despite these more defined estimates, there is a call for an international registry of patients with IPF, a movement that could also greatly enhance epidemiological estimates of drug-induced ILD.[305] Benefits associated with such a registry could include identification of key comorbidities, characterization of natural disease course, and provision of evidence to support advances in care.[305]

The incidence of ILD associated with specific drugs (Table 21-1) varies widely. Because ILD includes both pneumonitis and fibrosis, estimates can be inconsistent as pneumonitis is encountered more commonly. As mentioned previously, combined use of many of the implicated agents also renders incidence estimates variable. Lastly, most estimates of drug-induced ILD are obtained from case reports and observational studies, which can make identification of the true incidence difficult. For instance, the incidence of pulmonary toxicity associated with bleomycin in one study was estimated at 6.8%; however, this effect was highly dose dependent, with higher doses conferring a hazard ratio (HR) of 4.3 (95% CI 2.2–8.2) compared to lower doses.[306] Carmustine-induced lung injury follows a similar pattern and also appears more common in females due to differences in pharmacokinetics.[212] The incidence of ILD among patients treated with gefitinib has been estimated to be as high as 8% among Japanese patients in clinical trials but significantly lower (<1%) in other parts of the world, possibly as a result of differences in genetic susceptibility.[307]

MECHANISMS

The precise mechanism of drug-induced ILD is not well elucidated, although existing data have produced some theories regarding the pathophysiology. In IPF, it was originally hypothesized that fibrosis was the result of longstanding intra-alveolar inflammation and subsequent induction of fibrogenesis.[308] However, current research supports the concept that fibrosis may actually result from injury to alveolar epithelial cells and an induced state of abnormal wound healing.[308] Under this theory, microinjuries to the epithelium promote formation of a wound clot, increase secretion of growth factors, and increase proliferation of fibroblasts to the site of injury. Neovascularization develops, extracellular matrix is deposited, and alveolar epithelial cell death occurs, resulting in fibrosis.[308]

In drug-induced ILD, mechanisms may vary according to therapeutic class of the inciting agent (**Table 21-2**), as well as the patient's inherent genetic susceptibility.[121,124,133,236,309-314] It should be noted that the majority of proposed mechanisms of drug-induced ILD are theories at best, with limited evidence for confirmation. However, despite the fact that drugs may differ with respect to the events induced prior to lung insult, it is conceivable that drugs induce ILD via the same pathophysiological pathway as IPF, resulting in the similar appearance of fibrotic lesions from a radiological and histopathological perspective. The pathophysiology underlying drug-induced pneumonitis and fibrosis generally progresses over weeks to months, although the onset may be more rapid (days to weeks) for drugs with a hypersensitivity-type component associated with the induced pulmonary injury.[315]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The reduced lung compliance that is characteristic of pulmonary fibrosis is similar to that which occurs in other restrictive lung diseases. Therefore, the diagnosis of drug-induced ILD requires a thorough clinical history and exclusion of other known causes of ILD. The signs and symptoms of drug-induced ILD are listed in **Table 21-3**. Nearly all patients present with dyspnea, and some also experience a nonproductive cough.[316] The onset varies from days to weeks or even years, and is usually correlated with the duration of therapy with the causative agent. For instance, short-term use of an offending medication is more likely to present with acute onset ILD, whereas chronic therapy is likely to be associated with gradual development of symptoms, which the patient may or may not immediately recognize. With acute forms of drug-induced ILD, pneumonitis usually presents with acute shortness of breath, often with rash, wheezing, and peripheral eosinophilia. For more chronic ILD, progressive dyspnea and reduced exercise tolerance are commonly encountered. On physical examination, digital clubbing is present in 25–50% of patients, and end expiratory crackles are detected on auscultation in more than 80% of cases of IPF.[317] After progression to fibrosis, cyanosis and signs of pulmonary hypertension such as right ventricular dysfunction or peripheral edema may also be present.

Table 21-2 Mechanisms of Drug-Induced Interstitial Lung Disease/Pulmonary Fibrosis

Drug	Mechanism(s)
Nitrofurantoin	Generation of free oxygen radicals[309]
Methotrexate	Hypersensitivity reaction[310,311] Generation of free oxygen radicals[309]
Bleomycin	Activation of immune cells and inflammatory cascade Generation of free oxygen radicals[312] Deficiency of hydrolase activity[313]
Paclitaxel, docetaxel	Delayed hypersensitivity reaction[314]
EGFR inhibitors	Impairment of alveolar repair mechanisms[309]
Oxaliplatin	Depletion of glutathione[236]
Gemcitabine	Systemic release of cytokines causing endothelial dysfunction[309] Radiosensitizer[121]
Amiodarone	Induction of phospholipidosis[312] Disruption of lysosomal membranes through protein C activation and release of toxic oxygen radicals[309]
Lenalidomide	Prostaglandin inhibition and fibroblast proliferation[133]
HMG-CoA reductase inhibitors	Induction of phospholipidosis[124]

EGFR = epidermal growth factor receptor, HMG-CoA = 3-hydroxy-3-methylglutaryl-coenzyme A.

Table 21-3 Signs and Symptoms Associated with Drug-Induced Interstitial Lung Disease/Pulmonary Fibrosis

Signs/Symptoms

- Dyspnea (at rest and/or exertional)
- Nonproductive cough
- Crackles in lung bases
- Rash
- Wheezing
- Fatigue
- Digital clubbing
- Cyanosis

- Pulmonary hypertension
    - Peripheral edema
    - Right ventricular enlargement or failure
- Chest radiograph
    - Diffuse ground glass opacity
- HRCT
    - Diffuse opacity
    - Honeycombing
- PFTs
    - Reduced TLC or FVC
    - Reduced DL_{CO} >15% from baseline
- Laboratory tests
    - Leukocytosis
    - Eosinophilia
    - Elevated ESR

DL_{CO} = diffusion capacity of the lungs for carbon monoxide, ESR = erythrocyte sedimentation rate, FVC = forced vital capacity, HRCT = high resolution computed tomography, PFT = pulmonary function test, TLC = total lung capacity.

Pulmonary function tests (PFTs), widely obtained through the use of spirometry (which can be performed in office-based settings), should be completed during the diagnostic evaluation and monitoring for drug-induced ILD. Key measures include forced vital capacity (FVC; the amount of air forcefully exhaled after a full inspiration) and forced expiratory volume in one second (FEV_1; the amount of air expired in the first second of the FVC test). PFTs progress from normal to a restrictive pattern (reduced total lung capacity [TLC] and FVC) with the addition of reduced carbon monoxide diffusing capacity (DL_{CO}).[318] A reduced DL_{CO} by more than 15% from baseline indicates a pathologic disturbance of alveolar-capillary interface and resultant disruption of gas exchange, and should prompt further assessment. In practice, patients presenting with advanced ILD are often too deconditioned to perform PFTs, and arterial oxygen saturation is determined instead. Hypoxia at rest and with exertion is observed commonly.

Chest imaging should be obtained to diagnose drug-induced ILD. A chest radiograph may be useful to exclude edema or infection and is performed commonly, but it is neither sensitive nor specific for the diagnosis of drug-induced ILD.[318] In fully developed fibrosis, a chest radiograph reveals diffuse "ground glass" opacity and reduced lung volumes.[300] High resolution computed tomography (HRCT) is now a standard test in patients with suspected ILD. HRCT is 90% accurate in diagnosis of IPF and, when coupled with clinical findings and history, 60–80% accurate in diagnosis of drug-induced ILD.[317,318] The histopathological criteria for IPF are those of usual interstitial pneumonia, characterized by a honeycombing pattern from the subpleural cystic airspaces formed.

Bronchoscopy may be performed to obtain bronchoalveolar lavage samples with which to exclude infection and malignancy. Cell differentials with a lymphocytic, neutrophilic, or eosinophilic pattern can be useful for diagnosis when combined with clinical and radiographic data.[300] Transbronchial biopsies are not usually performed, as these tissue samples are too small to allow histological classification of ILD other than sarcoidosis. An open lung biopsy is definitive in the diagnosis of drug-induced ILD; however, it is not often a practical approach in patients with advanced ILD as the procedure can be associated with respiratory compromise, acute exacerbations, pulmonary hypertension, and increased mortality.

In general, laboratory data are not helpful in establishing the diagnosis of drug-induced ILD. Patients may have an elevated white blood cell count with increased eosinophils; however, absence of eosinophilia does not exclude the diagnosis.[318] Amiodarone-induced pulmonary toxicity is often associated with an elevated erythrocyte sedimentation rate; however, this does not contribute meaningfully to the diagnosis.[319] Testing for antinuclear antibodies, anticytoplasmic antibodies, and antiglomerular basal membrane autoantibodies is essential if there is concern regarding the potential for diffuse alveolar hemorrhage, as these antibodies differentiate autoimmune versus nonautoimmune causes.[319]

Because drug-induced ILD is a diagnosis of exclusion, there are several considerations in the differential diagnosis (**Table 21-4**), which may only be distinguished by a positive history of exposure to a causative agent. The symptoms, physical findings, laboratory information, and imaging studies are similar in nearly all types of ILD including connective tissue disease with pulmonary fibrosis, IPF, and certain pneumonias such as those induced by viruses or *Pneumocystis jiroveci*.[31] It should be noted that patients with drug-induced ILD often have pre-existing conditions that increase their risk of lung injury (**Table 21-5**). One proposed set of criteria for the diagnosis of carmustine-induced ILD, which may be applicable to other types of drug-induced ILD, are (1) typical symptoms of nonproductive cough and dyspnea with or without fever; (2) decrease of DL_{CO} capacity by >10% as compared with baseline; and (3) no clinical evidence of active pulmonary infection.[320]

Table 21-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Interstitial Lung Disease/Pulmonary Fibrosis

Conditions

- Acute respiratory distress syndrome
- Aspiration pneumonitis
- Bronchiolitis obliterans organizing pneumonia (nondrug-induced)
- Connective tissue disease–related pulmonary fibrosis
- Heart failure
- Hyperthyroidism
- Hypoxemia
- Idiopathic pneumonia syndrome after bone marrow transplantation
- Idiopathic pulmonary fibrosis

- Miliary tuberculosis
- *Pneumocystis jiroveci* pneumonia
- Radiation pneumonitis
- Systemic lupus erythematosus
- Viral infection
- Wegener granulomatosis

RISK FACTORS

In general, the likelihood of developing pulmonary toxicity from drugs is unpredictable. Although several risk factors have been identified (Table 21-5), none are consistent for all drugs or patient populations. Patients at risk of developing drug-induced ILD include those with cancer or inflammatory conditions receiving chemotherapy or concurrent therapy with multiple toxic agents. Dose-related toxic effects have been identified in the development of drug-induced ILD for several drugs. Risk factors for lung toxicity associated with amiodarone are a combination of daily dose (>400 mg daily) and duration of therapy (cumulative dose).[319] The risk for pulmonary toxicity is greatest at cumulative doses above 1,400 mg/m^2 for carmustine and above 360 units for bleomycin.[46,216] However, ILD has also been reported at low doses of these drugs, and therefore a strong association between dose and pulmonary toxicity does not always exist. In general, extremes of age can be associated with an increased risk of lung toxicity, depending on the drug. The incidence of bleomycin-induced pulmonary fibrosis increases in patients older than 70 years of age, possibly as a result of diminished antioxidant defenses and impaired drug clearance.[45,306] Conversely, an inverse relationship between age and carmustine-induced pulmonary toxicity has been suggested, with patients under 7 years of age at greatest risk.[214,216]

Table 21-5 Risk Factors for Drug-Induced Interstitial Lung Disease/Pulmonary Fibrosis

Risk factors

- Age (young or old)
- Concomitant use of other cytotoxic drugs
- Dose
    - Amiodarone >400 mg daily
    - Carmustine >1,400 mg/m^2 cumulative
    - Bleomycin >360 units cumulative
- Drug interactions (increased drug concentration or concomitant use of drugs that compound risk)
- Environmental factors (e.g. asbestos, cigarette smoke)
- Genetic factors
- Oxygen therapy (high concentration, e.g., 60% or more FiO$_2$)

- Radiation therapy (mantle, thoracic, total body)
- Underlying obstructive or restrictive lung disease

FiO_2 = fraction of inspired oxygen.

Environmental factors, such as exposure to asbestos and cigarette smoke, can increase the risk of pulmonary toxicity. It is unknown whether a history of pulmonary adverse effects associated with a specific drug or related compounds increases the risk for future lung toxicity. Certain genetic and other factors may be important in the development of drug-induced ILD. Acute and organizing diffuse alveolar damage associated with bortezomib was first reported in Japan and then in African-American patients, and higher rates of gefitinib-induced ILD have been noted for Japanese patients compared to other populations.[307,321,322] Genetic polymorphisms may explain some differences in drug toxicity across populations, but intrinsic and disease-related sensitivity to ILD in general may cloud the picture. For instance, Japanese patients with rheumatoid arthritis and the HLA-A*31:01 allele may be at higher risk of methotrexate-induced ILD, while HLA-B40, B54, and DR4 antigen sites have been related more generally to increased susceptibility for ILD in the setting of rheumatoid arthritis (for which methotrexate is a commonly used therapy).[323] Concomitant therapies and conditions that may influence the cytochrome P-450 system or detoxification pathways or alter pharmacokinetics of the offending agent may also increase risk of toxicity.[324] Concomitant therapy with radiation or high fractions of inspired oxygen (e.g., >60%) are associated with an increased risk of drug-induced ILD.[324] Radiation therapy can injure lung deoxyribonucleic acid (DNA) and proteins associated with lung tissue repair, which can exert a synergistic effect with drug-induced pulmonary toxicity. The risk associated with oxygen is similar, as higher concentrations of oxygen generate reactive metabolites, leading to further oxidative stress. Underlying disease is known to play a role, primarily in the presence of pre-existing pulmonary disease.[324] However, this association is controversial. The risk of bleomycin-induced pulmonary fibrosis may be increased in patients with kidney disease due to impaired drug clearance. A glomerular filtration rate of <80 mL/min was found to be an independent risk factor for development of bleomycin-induced pulmonary toxicity.[306]

MORBIDITY AND MORTALITY

The morbidity associated with drug-induced ILD from personal, societal, or financial perspectives has not been described; however, it is likely substantial due to the potential impact of pulmonary symptomology (dyspnea, persistent cough, etc.) on the ability to work and conduct activities of daily living. Some data describing healthcare utilization specific to IPF are available. In one case-control analysis, patients with IPF incurred all-cause hospitalizations (0.5/person/year), hospital days (3.1 days/person/year), and outpatient visits (28 visits/person/year) at approximately twice the rate of controls, with an extrapolated incremental IPF-associated cost estimated at over $1 billion/year.[325]

Mortality figures for ILD are imprecise for a number of reasons, including comorbidities in patients that may render the cause of death unclear (lung cancer, cerebrovascular disease, pneumonias) or the lack of a classification system for the various forms of ILD.[301] Pulmonary fibrosis (both idiopathic and otherwise), as the progressive endpoint of ILD, has generated some global figures. Using data from the National Center for Health Statistics, median survival for patients with pulmonary fibrosis was estimated to be 3–5 years, with an average age- and sex-adjusted mortality rate of 50.8 per 1,000,000.[326] Mortality was higher among men, although deaths in women increased at a faster rate (41.3%) over the 1992–2003 study period compared to men (28.4%).[326] In the UK-based study of drug- and radiation-induced ILD, the risk of death was found to be 7 times greater (HR 7.13, 95% CI 3.40–14.93) among those with ILD compared to population-matched controls.[302]

Because of the heterogeneity of conditions under the ILD umbrella, a multidimensional index—the modified gender, age, and physiology (GAP) model—has been created to predict mortality in patients with ILD.[327,328] First established specifically for IPF and then generalized to other ILD, the model assigns points based on gender, age, and physiology including FVC % predicted and DL_{CO} % predicted as well as subtype of ILD.[328] Scores can then be correlated to 1-, 2- and 3-year predicted mortality rates.[328] For instance, a nonelderly woman with IPF and preserved lung function could expect a 1-year mortality rate of 3.1%, compared to 18.2% in an elderly man with the same condition but with pulmonary function at 50% of predicted.[328] This tool may help clinicians better evaluate patients with ILD; however, it should be noted that this index is not specific to drug-induced forms of ILD and may only be applicable broadly.

Mortality rates for ILD induced by specific drugs are of greater pertinence. Mortality due to pneumonitis associated with bleomycin has been estimated at approximately 10 to 20%.[329] Among a case series literature review of 123 patients with methotrexate-induced pneumonitis, the respiratory-related fatality rate was 13%.[142] Mortality due to amiodarone-induced pneumonitis has been estimated at 10%, although it may be 2–3 times higher in those requiring hospital admission.[14] A recent review of seven classes of targeted therapies for non-small-cell lung cancer (EGFR inhibitors, anaplastic lymphoma kinase inhibitors, angiogenesis inhibitors, tyrosine kinase [TK] inhibitors, human epidermal growth factor receptor 2 [HER2] inhibitors, anti-CD20 antibodies, and mammalian target of rapamycin inhibitors) reported a wide range of mortality rates.[330] For instance, among reports of ILD induced by gefitinib, erlotinib, and sorafenib, mortality rates were estimated at

>30%, while ILD-related deaths among patients receiving rituximab, temsirolimus, and everolimus were significantly less common.[330]

PREVENTION

Prevention of drug-induced ILD should focus on avoidance of potentially causative agents in patients who are at risk and careful selection for use in other populations. Other general strategies are summarized in **Table 21-6**. In general, the lowest effective dose of a drug should be utilized so as to avoid excessive exposure and additional associated risk of drug-induced ILD. Beyond careful dose selection, there remains minimal evidence supporting strategies for prevention or risk reduction. All recommended strategies focus on frequent screening to maximize the likelihood of early diagnosis. In patients at risk for drug-induced ILD, pretreatment and routine on-treatment PFTs should be determined because a change may be indicative of toxicity development; however, reductions in TLC and FVC may not become evident until after disease is established. The measurement of DL_{CO} should be considered for patients taking drugs associated with a high incidence of pulmonary fibrosis (Table 21-1), although little is known about whether this reduces the incidence or simply aids in more prompt diagnosis.[331] In addition, the significance of asymptomatic reductions in DL_{CO} is unknown. Monitoring frequency is largely left to the discretion of healthcare providers and tends to be both patient-specific and drug-dependent, with usual frequency of every 2 weeks to every 2–4 months.[332] The positive predictive value of serial DL_{CO} monitoring with spirometry for amiodarone-induced pulmonary toxicity is 21%.[333] Despite this low value, it is recommended to consider chest radiography, PFTs, and DL_{CO} monitoring prior to initiation of therapy and every 3–6 months in patients taking maintenance amiodarone therapy.[319] Monitoring of DL_{CO} and PFTs is probably less likely to detect early disease for patients taking drugs with lower rates of pulmonary fibrosis. As discussed previously, HRCT is a more sensitive test for diagnosis of drug-induced ILD, but there is no evidence supporting HRCT in the routine monitoring for drug-induced pneumonitis.[9]

Table 21-6 Approaches to Help Prevent Drug-Induced Interstitial Lung Disease/Pulmonary Fibrosis

Prevention and early detection

- Use lowest dose for shortest duration possible for desired effect
- Avoid combinations of drugs known to increase risk
- Frequent follow-up to monitor for symptoms of dyspnea and nonproductive cough
- PFTs and DL_{CO} at baseline and every 2 weeks to every 2–4 months for high-risk drugs

- Consider chest radiograph every 3–6 months for high-risk drugs
- Consider HRCT every 6 months for high-risk drugs
- Inhaled corticosteroids (fluticasone 880 mcg every 12 hours) for prophylaxis of carmustine-induced pulmonary toxicity

DL_{CO} = diffusion capacity of the lungs for carbon monoxide, HRCT = high resolution computed tomography, PFT = pulmonary function test.

Limited options exist for pharmacologic prevention of drug-induced ILD. Inhaled corticosteroids have been studied for prophylaxis of carmustine-associated lung toxicity in patients with breast cancer.[334] Inhaled fluticasone 880 mcg every 12 hours preserved pulmonary function and decreased the incidence of pulmonary toxicity in patients with breast cancer treated with a conditioning regimen of cyclophosphamide, cisplatin, and carmustine for autologous stem cell transplantation.[335] Some prevention strategies for drug-induced ILD with other medications show early promise. Inhibition of HER2 with recombinant monoclonal antibodies may reduce the risk of bleomycin-induced pulmonary toxicity.[336] In addition, thalidomide reduced the incidence of bleomycin-induced pulmonary toxicity in a mouse model, possibly due to its known inhibitory effect on interleukin-6–dependent cell growth.[337] Finally, two therapies in development, JNJ7777120 plus naproxen and NCX 466, which target a dual mechanism with a cyclooxygenase inhibitor and nitric oxide donor, both reduced incidence of bleomycin-induced pulmonary fibrosis.[338,339] However, further research in prevention strategies for ILD associated with all causative medications continues to be warranted.

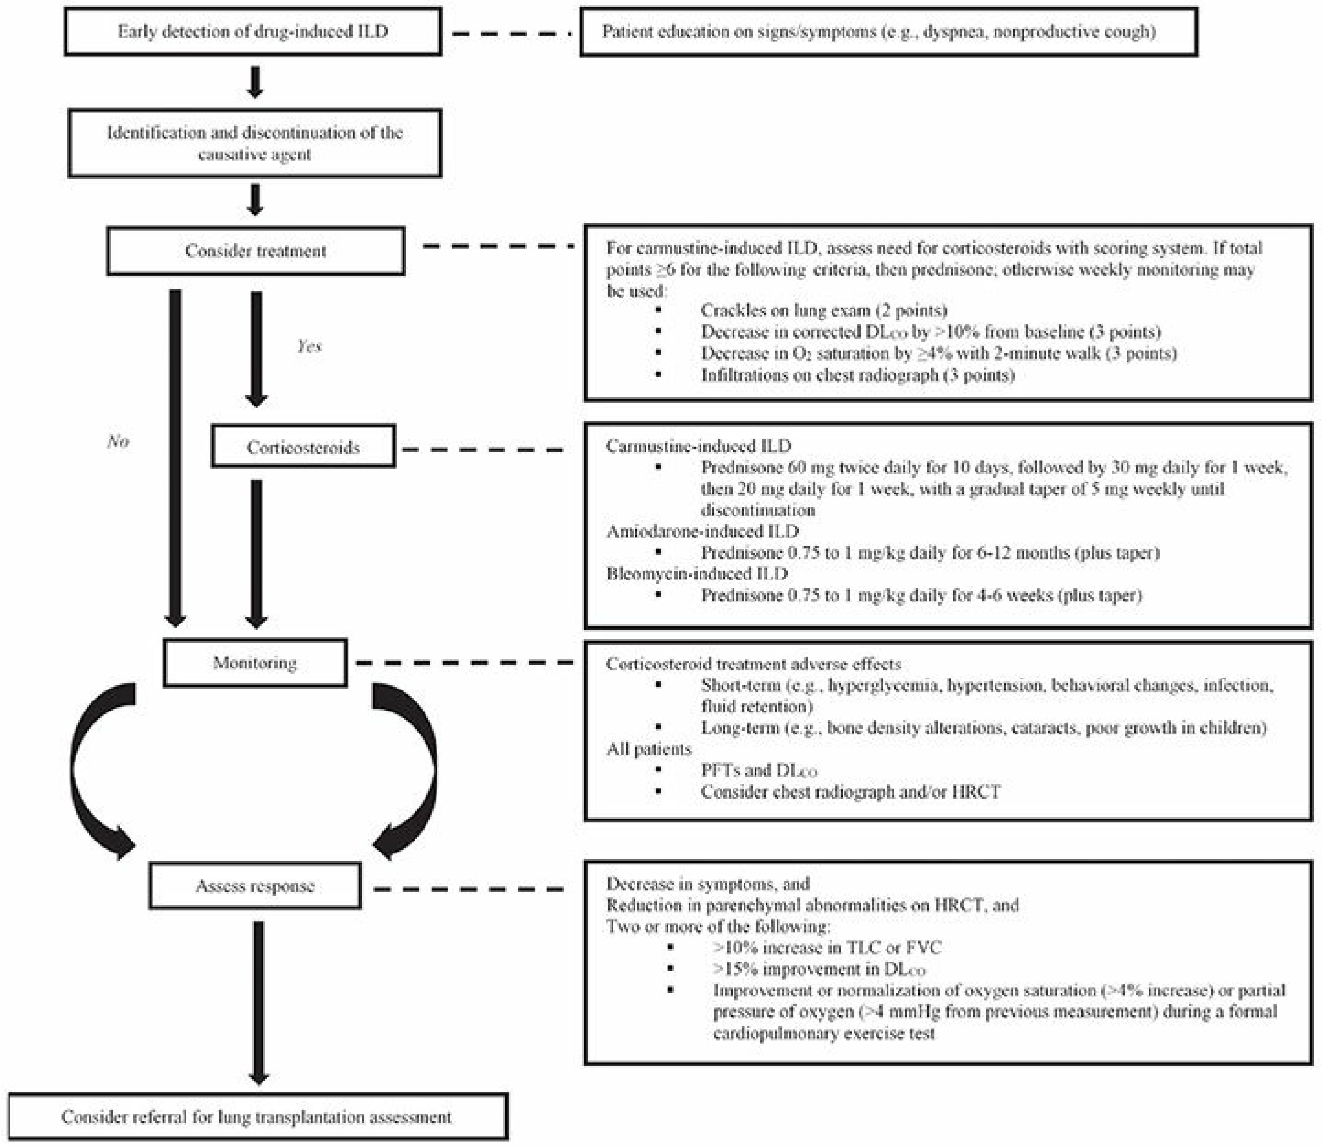
MANAGEMENT

The goals of drug-induced ILD management include early detection, discontinuation of the causative agent, and, in some cases, initiating corticosteroid therapy. Monitoring for signs and symptoms of drug-induced pulmonary fibrosis is essential, in view of the fact that, in most documented cases, a positive clinical response has been reported within the first 7–10 days after discontinuing the causative agent and initiating therapy with corticosteroids. In some cases, positive response may occur even sooner. Acute episodes of drug-induced ILD such as pneumonitis may resolve within 48 hours after discontinuation of the causative agent. However, pulmonary fibrosis may take longer to resolve, if improvement occurs at all. The primary goal of any treatment option is to inhibit the inflammatory response and prevent deposition and progression of fibrotic tissue. Extrapolating guidelines for management of IPF, a favorable response is depicted by a decrease in symptoms, reduction in parenchymal abnormalities on HRCT, and two or more of the following: (1) >10% increase in TLC or FVC, (2) >15% improvement in DL_{CO}, or (3) improvement or normalization of oxygen saturation (>4% increase) or partial pressure of oxygen (>4 mm Hg from previous measurement) achieved during a formal cardiopulmonary exercise test.[317] If improvement does not occur, however, referral to a lung transplantation center is an important consideration, given that some patients with IPF or drug-induced ILD benefit from a lung transplant.[317]

Historically, corticosteroid therapy is regarded as the standard treatment for drug-induced ILD, although compelling evidence supporting this practice is lacking for most forms of ILD. Of note, standard doses of corticosteroid therapy have not been established, and the risk of adverse drug reactions such as immune system compromise, hypertension, hyperglycemia, fluid retention, and bone density alterations must be considered prior to initiation of therapy.

More data exist regarding treatment options for IPF than for drug-induced ILD. The American Thoracic Society (ATS) guidelines for IPF do not recommend the use of corticosteroid monotherapy or corticosteroids in combination with cyclophosphamide (a historic and empirically used therapy for IPF), due to the lack of evidence supporting any survival benefit.[317] Guidance also recommends against use of several other therapies including colchicine, imatinib, acetylcysteine alone or in combination with corticosteroids and azathioprine, or endothelin receptor antagonists.[317] The ATS guidelines, however, recommend the use of nintedanib or pirfenidone, two novel therapies approved for use in IPF in 2014.[317] Treatment with nintedanib, a TK inhibitor, has been associated with an increased likelihood of preserving lung function and fewer acute exacerbations in patients with mild-to-moderate IPF.[340,341] Pirfenidone is an oral antifibrotic medication associated with a reduction in mortality, FVC decline, and improved symptoms in patients with IPF.[342,343] It should be emphasized that these agents are currently only FDA-approved for use in IPF, and therefore other types of ILD (drug-induced or otherwise) are unapproved indications.

Treatment recommendations exist for ILD induced by specific drugs, including carmustine, bleomycin, and amiodarone. An algorithm to help guide treatment is provided in **Figure 21-1**. For management of carmustine-induced ILD, a clinical scoring system has been developed to determine the necessity for adjunctive corticosteroids during carmustine therapy for breast cancer.[334] Patients with a score ≥6 were initiated on prednisone therapy (60 mg twice daily for 10 days, followed by 30 mg daily for 1 week, then 20 mg daily for 1 week, with a gradual taper of 5 mg weekly until discontinuation), while patients with a score <6 were monitored weekly.[334] The prednisone regimen produced clinical improvement within 72 hours of initiation with no patients progressing to chronic pulmonary fibrosis or death.[334] Therefore, corticosteroids may inhibit development of carmustine-induced chronic pulmonary fibrosis when initiated upon early signs of acute toxicity.



Early detection of drug-induced ILD
Patient education on signs/symptoms (e.g., dyspnea, nonproductive cough)
Identification and discontinuation of the causative agent
Consider treatment
For carmustine-induced ILD, assess need for corticosteroids with scoring system. If total points ≥6 for the following criteria, then prednisone; otherwise weekly monitoring may be used:
Crackles on lung exam (2 points)
Decrease in corrected DLco by >10% from baseline (3 points)
Decrease in O2 saturation by ≥4% with 2-minute walk (3 points)
Infiltrations on chest radiograph (3 points)
Yes
No
Corticosteroids
Carmustine-induced ILD
Prednisone 60 mg twice daily for 10 days, followed by 30 mg daily for 1 week, then 20 mg daily for 1 week, with a gradual taper of 5 mg weekly until discontinuation
Amiodarone-induced ILD
Prednisone 0.75 to 1 mg/kg daily for 6-12 months (plus taper)
Bleomycin-induced ILD
Prednisone 0.75 to 1 mg/kg daily for 4-6 weeks (plus taper)
Monitoring
Corticosteroid treatment adverse effects
Short-term (e.g., hyperglycemia, hypertension, behavioral changes, infection, fluid retention)
Long-term (e.g., bone density alterations, cataracts, poor growth in children)
All patients
PFTs and DLco
Consider chest radiograph and/or HRCT
Assess response
Decrease in symptoms, and
Reduction in parenchymal abnormalities on HRCT, and
Two or more of the following:
>10% increase in TLC or FVC
>15% improvement in DLco
Improvement or normalization of oxygen saturation (>4% increase) or partial pressure of oxygen (>4 mmHg from previous measurement) during a formal cardiopulmonary exercise test
Consider referral for lung transplantation assessment

FIGURE 21-1 Treatment Algorithm for Selected Agents in Drug-Induced Interstitial Lung Disease/Pulmonary Fibrosis

DL_{CO} = diffusion capacity of the lungs for carbon monoxide, FVC = forced vital capacity, HRCT = high resolution computed tomography, ILD = interstitial lung disease, PFTs = pulmonary function tests, TLC = total lung capacity.

For management of bleomycin-induced ILD, drug discontinuation and corticosteroid therapy are recommended. No specific doses have been studied, but prednisone 0.75–1 mg/kg daily for an initial 4–6 weeks (followed by a careful and gradual taper) to assess clinical response is a reasonable option. Drugs that have been investigated in animals include thalidomide, curcumin, aerosolized heparin, aerosolized urokinase, and oral acetylcysteine.[336,344-346] Pirfenidone therapy was initiated in two patients who experienced severe bleomycin pulmonary toxicity; however, both patients died.[347] Prospective trials are needed to better establish any potential benefit of drug therapy for treatment of bleomycin-induced ILD.

Some limited evidence supports the use of corticosteroids for the management of amiodarone-induced pulmonary toxicity. Amiodarone-induced lung injury can be particularly difficult to manage because some patients require continued treatment for refractory arrhythmia management, even in the presence of pulmonary fibrosis. Prednisone (0.75–1 mg/kg daily) is often administered until clinical and radiographic improvement occurs, with tapering of therapy recommended. The total corticosteroid treatment duration for amiodarone-induced lung toxicity should be approximately 6–12 months, due to the long half-life of amiodarone and the risk of recurrence. Early discontinuation of corticosteroid therapy has resulted in recurrence of amiodarone-induced pulmonary fibrosis.[319]

INFORMATION FOR PATIENTS

Healthcare providers must guide patients in their understanding of the risk of drug-induced ILD. Patients should be reminded of the balance of risks and benefits of the associated therapies. Patients should understand the risk factors associated with drug-induced ILD, as well as the common symptoms of shortness of breath and nonproductive cough.[348] It should be emphasized to notify the prescriber immediately of any of these symptoms in order to detect early signs of pulmonary toxicity. All patients should be counseled to cease tobacco use prior to starting therapy with any medication associated with drug-induced ILD. Finally, in the event that drug-induced ILD occurs, providers should ensure patient understanding of the disease. All relevant medical specialties should weigh in on the decision regarding optimal therapies for the disease upon cessation of the offending agent. If patients receive corticosteroids, counseling regarding adverse effects and referrals for dietitian and exercise programs to manage these effects should be emphasized. Communication about drug-induced ILD between patients and their providers is critical for effective management due to the risk of rapid progression and high mortality rates associated with the disease.

CHAPTER 22

Asthma and Bronchospasm

Suzanne G. Bollmeier and Rebecca L. Stauffer

Asthma is a common disease affecting approximately1–18% of the population in different countries worldwide[1] and is characterized by airway inflammation, bronchial hyperresponsiveness, and airway obstruction that is usually reversible spontaneously or with treatment. Airway obstruction causes most of the clinical signs and symptoms of asthma, which include shortness of breath and bronchospasm, cough, mucus secretion, and bronchial hyperresponsiveness. Acute asthma exacerbations, or deterioration in status, can be triggered by several factors, including airborne pollens, dust, animal dander, and chemicals, as well as medications.[2] Among known asthma triggers, medications are perhaps the least common.[3] Drugs can lead to bronchospasm by a variety of mechanisms, and drug-induced bronchospasm may present as an isolated event or as a symptom of immunologic (anaphylaxis) or nonimmunologic (anaphylactoid) reactions.[4] Although drug-induced bronchospasm occurs primarily in patients with pre-existing asthma, it may also occur in patients with other forms of airway hyperresponsiveness or drug allergies.[5]

CAUSATIVE AGENTS

Drugs that have been reported to cause bronchospasm or worsen asthma symptoms are listed in **Table 22-1**.[6-103] Most evidence comes from case reports, but for some medications, stronger evidence exists. Although bronchospasm occurs rarely in association with most of the listed causative agents, aspirin, nonsteroidal anti-inflammatory agents (NSAIDs), β-adrenergic receptor antagonists (β-blockers), radiocontrast dyes, sulfites, and angiotensin-converting enzyme (ACE) inhibitors can cause bronchospasm more frequently.[3]

EPIDEMIOLOGY

The prevalence of asthma is increasing, especially among children, in many areas of the world, including Africa, Latin America, Eastern Europe, Asia, and the United States.[104] For example, in the United States, the prevalence of asthma increased by 14.8% in less than 10 years (2001–2010).[105] The overall incidence of drug-induced bronchospasm is unknown.

Table 22-1 Agents Implicated in Drug-Induced Asthma and Bronchospasm

Drug	Incidence	Level of Evidence[a]
Acetaminophen[6-8]	0–32%	A
N-acetylcysteine[9]	NK	B
α-agonists[10]	NK	C
Amiodarone[11,12]	NK	C
Angiotensin-converting enzyme inhibitors[13-16]	0–44% (cough) NK (bronchospasm)	A
Aspirin[17-19]	4–44%	A
Benzalkonium chloride[20,21]	NK	A
β-blockers[22,23]	NK	A
Betahistine[24]	NK	C
Bromelin[25]	NK	C
Carbamazepine[26]	NK	C
Carboprost[27]	NK	C
Cisapride[28]	NK	C
	NK	C

Cocaine[29,30]		
Colistin[31]	NK	A
Cromolyn[32]	NK	C
Cyclophosphamide[33]	NK	C
D-tubocurarine[34-36]	NK	C
D-penicillamine[37,38]	NK	C
Desensitization extracts[39]	NK	C
Dipyridamole[40]	NK	B
Estrogen[41,42]	NK	B
Ethanol[43]	NK	B
Ethylenediaminetetraacetic acid[44-46]	NK	A
Etidronate[47]	NK	C
Gallamine[48]	NK	C
Glucosamine and chondroitin[49]	NK	C
Heroin[50,51]	NK	B
Hydrocortisone sodium succinate[52,53]	2%	A
Interferon alfa[54]	NK	C
Interleukin-2[55,56]	NK	A
Iodinated radiocontrast media[57]	0.22–1%	B
Isotretinoin[58,59]	NK	C
Losartan[60,61]	NK	C
Menthol[62]	NK	C
Meperidine[63]	NK	C
Methimazole[64]	NK	C
Methotrexate[65,66]	NK	C
Methyldopa[67]	NK	C
Methylprednisolone[68,69]	NK	C
Mivacurium[70]	NK	C
Neostigmine[71]	NK	C
Nonsteroidal anti-inflammatory drugs (COX-1)[72-75]	4–44%	A
Oxytocin[76]	NK	C
Pancuronium bromide[77]	NK	C

Pentazocine[78]	NK	C
Pentamidine[79-81]	NK	A
Propafenone[82]	NK	A
Propofol[83]	NK	C
Propylthiouracil[84]	NK	C
Psyllium[85,86]	5–12%	B
Pyrethrin[87,88]	NK	C
Sodium benzoate[89]	NK	C
Sodium salicylate[90]	NK	C
Sulfites[91,92]	5–11%	A
Tamoxifen[93]	NK	C
Tartrazine[94,95]	0–2.4%	B
Tetramethrin[96]	NK	C
Tobramycin[97-99]	NK	A
Venlafaxine[100]	NK	C
Verapamil[101]	NK	C
Yohimbine[102]	NK	C
Zanamivir[103]	NK	C

COX = cyclooxygenase, NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Aspirin can exacerbate symptoms in patients with diagnosed asthma. A recent meta-analysis found the prevalence to be 7% in typical adult patients with asthma, and as high as 14% in those with severe asthma at baseline.[17] Aspirin-induced bronchospasm in patients without a prior diagnosis of asthma is rare, with a prevalence of <1%.[18,19] Due to similar mechanisms, patients with aspirin-exacerbated respiratory disease (AERD) also experience symptoms of asthma or bronchospasm associated with NSAIDs that inhibit cyclooxygenase-1 (COX-1). NSAID-associated hypersensitivity occurs in approximately 26% of patients with asthma.[72] Drugs that are poor inhibitors of COX-1 (acetaminophen and nonacetyl salicylates such as salsalate) and highly selective COX-2 inhibitors (celecoxib) are generally safe to use in this patient population.[73] However, there are case reports of COX-2 inhibitors, such as celecoxib, inducing asthma attacks.[74,75] Meloxicam is a partially selective inhibitor of COX-2 but may be tolerated in aspirin-intolerant patients.[106]

The prevalence of acetaminophen-induced bronchospasm in aspirin-sensitive patients with asthma is 0–6% with single doses ≤650 mg,[8] and most patients can tolerate single acetaminophen doses ≤500 mg.[107] A case-control study evaluating the cross-reactivity of acetaminophen in aspirin-intolerant patients reported bronchospasm in 24% and 32% after an oral challenge with acetaminophen 1,000 mg or 1,500 mg, respectively. No patient with aspirin-tolerant asthma developed acetaminophen-associated bronchospasm.[8] Furthermore, case-control studies have found that increasing frequency of acetaminophen use is associated with asthma in adults.[6,7]

Guidelines recommend against the routine use of β-blockers in patients with asthma, and some experts consider them contraindicated.[2,108] However, due to their beneficial effects on cardiac morbidity and mortality following events such as a myocardial infarction and in patients with heart failure with reduced ejection fraction (HFrEF), β-blockers are often prescribed to patients even with respiratory diseases including asthma. It is estimated that 2.2% of patients with asthma are prescribed β-blockers every year.[23] The prevalence of bronchospasm associated with nonselective β-blockers is unknown, but it has been estimated that 50–100% of patients with asthma exhibit symptoms of bronchospasm after a single dose of a nonselective β-blocker.[3,22] In addition to problems caused by oral or intravenous administration of these drugs, fatal asthma has also been reported in association with ophthalmic administration of timolol.[109,110] Cardioselective β-blockers decrease the risk of, but do not eliminate, β-blocker–induced bronchospasm.[23] Decreased forced expiratory volume in 1 second (FEV_1) and symptoms of bronchospasm have been demonstrated in asthmatic patients receiving cardioselective β-blockers.[23] However, two meta-analyses evaluating the safety of cardioselective β-blockers in patients with reactive airway disease concluded that these agents do not produce clinically significant adverse respiratory effects in this population.[23,111] Also, cardioselective β-blockers were found to be well tolerated in trials that included patients with cardiovascular diseases, including hypertension, angina, and heart failure.[111]

ACE inhibitor-induced cough appears to be a class effect.[13] The prevalence of ACE inhibitor-induced cough in the general population is approximately 5–35%.[13] Interestingly, nonsmoking patients are thought to be at higher risk.[14] Cigarette smoking is believed to negatively impact the cough reflex; therefore, nonsmokers may be more likely to respond to a normal cough reflex exacerbated by an ACE inhibitor. The prevalence of ACE inhibitor-induced cough and bronchospasm in patients with reactive airway disease appears to be similar to that in the general population.[15] Although the incidence of cough and bronchospasm associated with angiotensin receptor blockers (ARBs) is low, and they are often used in patients with ACE inhibitor-induced cough, cases of bronchospasm and cough have been reported in patients taking losartan.[60]

Paradoxical bronchospasm is an unexpected bronchoconstriction associated with inhaled bronchodilators.[112] Although rare, paradoxical bronchospasm associated with bronchodilators delivered by metered-dose inhaler or nebulization has been reported.[46,113-116] This underrecognized reaction may occur in up to 1% of salbutamol inhalations.[112] The cause is unknown, but it is postulated that propellants, preservatives, or the osmolality or pH of the inhalant may play a role.[117] Bronchospasm occurs in up to 6.9% of asthmatic patients following inhalation from a placebo metered-dose inhaler containing only inert ingredients.[118] The incidence of bronchospasm decreases from 4% to 1.55% when active drug is added.[119] Inactive ingredients in metered-dose inhalers implicated include chlorofluorocarbons, sorbitan trioleate, oleic acid, and soya lecithin.[119] Some reports have also implicated newer metered-dose inhalers containing hydrofluoroalkane delivery systems as a cause of paradoxical bronchospasm as many of these inhalers contain similar inert ingredients.[113,114,120,121]

Similarly, preservatives like benzalkonium chloride and medication additives including sulfites,sodium benzoate, and ethylenediamine tetraacetic acid (EDTA) can cause asthma symptoms.[21,89,115] Sulfites are no longer used in inhaled asthma drugs. However, sulfites are still used in injectable forms of isoproterenol and epinephrine. Sulfite-induced bronchospasm rarely occurs in patients without airway hyperresponsiveness.[119] The prevalence of sulfite sensitivity in patients with asthma is 5–11% and increases with age in children with severe asthma.[119,122,123]

Benzalkonium chloride is a common preservative used as a bacteriostatic agent used in nebulizer solutions.[115] EDTA is a stabilizing agent that is also found in some nebulizer preparations. Both compounds have been implicated as a potential cause of paradoxical bronchoconstriction induced by nebulized medications.[115,119,124] Benzalkonium chloride may stimulate histamine release from mast cells,resulting in cumulative dose-related bronchoconstriction.[115,119] EDTA is added to some pharmaceutical preparations as a chelating agent to prevent solution discoloration.[124] Although EDTA has been shown to cause bronchoconstriction when large doses are inhaled, clinically important bronchospasm did not occur when concentrations similar to those found in commercial products were used.[45,115,125]

MECHANISMS

Several mechanisms are associated with drug-induced asthma or bronchospasm. Most reports of bronchospasm are isolated cases, and the mechanism is unknown. Mechanisms of bronchospasm associated with individual drugs, when known, are listed in **Table 22-2**.[8,9,23,126-131]

Table 22-2 Mechanisms of Drug-Induced Asthma and Bronchospasm

Drug	Mechanism
Acetaminophen[8]	Not clearly understood; weak inhibition of cyclooxygenase
N-acetylcysteine[9]	Airway irritation
Angiotensin-converting enzyme inhibitors[126]	Not clearly understood; may be related to increased concentrations of bradykinin and substance P with related alterations in prostaglandin homeostasis
Aspirin[127]	Inhibition of COX forces the metabolism of arachidonic acid through the lipoxygenase pathway, resulting in increased concentrations of leukotrienes (see Figure 22-1)
Benzalkonium chloride[128]	Anaphylactoid mast-cell degranulation and stimulation of cholinergic and noncholinergic nerves in the airways
β-blockers[23]	β_2-receptor blockade, leading to bronchoconstriction
Nonsteroidal anti-inflammatory drugs (COX-1 inhibitors)[129]	Inhibition of COX forces the metabolism of arachidonic acid through the lipoxygenase pathway, resulting in increased concentrations of leukotrienes (see Figure 22-1)
Sulfites[130,131]	Sulfur dioxide is liberated during nebulization; inhalation can lead to increased concentrations of proinflammatory mediators such as interleukin-6 and tumor necrosis factor α

COX = cyclooxygenase.

Bronchospasm can be provoked by direct irritation of the airway from *N*-acetylcysteine or bisulfites, IgE-mediated reactions in anaphylaxis, precipitation of IgG antibodies that may occur in association with methyldopa, mast-cell degranulation, or as a result of an intended or unintended pharmacologic effect in patients taking aspirin or β-blockers.[132] Aspirin-exacerbated respiratory disease is characterized by airway inflammation and hyperresponsiveness associated with drugs that inhibit COX-1 such as aspirin and NSAIDs.[127] This nonallergic hypersensitivity is characterized by an association between aspirin intolerance, asthma, nasal polyps, and chronic rhinosinusitis, referred to as the aspirin tetrad.[127] The mechanism of AERD is not completely understood. It is unlikely that the response to aspirin is caused by an IgE-dependent mechanism but is more likely due to inhibition of COX-1 and prostaglandin synthesis. This leads to activation of inflammatory mast cells, eosinophils, and the subsequent release of leukotrienes and other mediators within the nasal mucosa.[72] Currently proposed mechanisms of AERD are presented in **Figure 22-1**.[133]

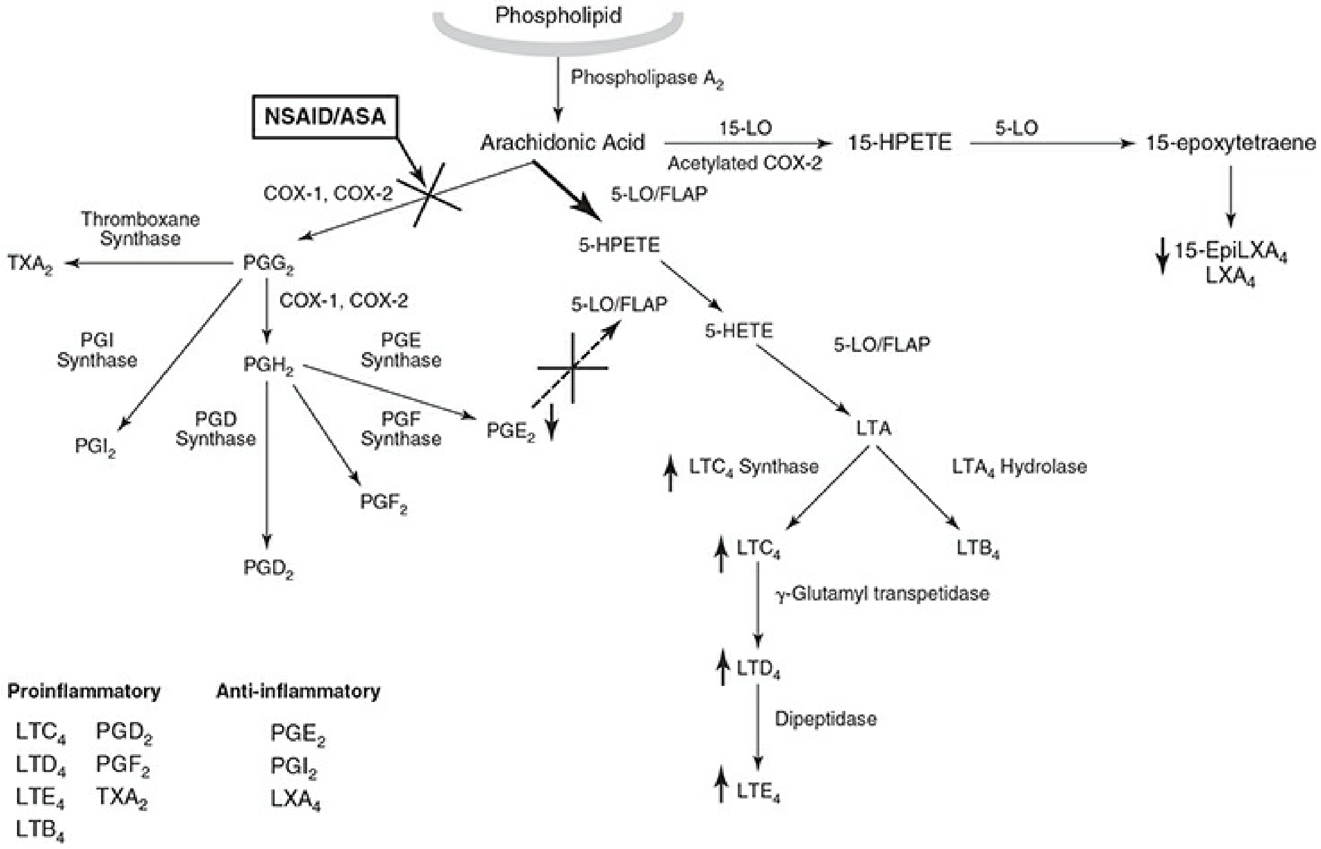

FIGURE 22-1 Mechanisms of Aspirin-Exacerbated Respiratory Disease

Aspirin/NSAID inhibition of cyclooxygenase (COX-1, COX-2) pathways forces the metabolism of arachidonic acid through the lipoxygenase pathway. Decreased prostaglandin E_2 production and increased leukotriene synthase activity results in increased production of the proinflammatory cysteinyl leukotrienes. Production of lipoxin and lipoxin epimers also appears to be decreased. ASA = acetylsalicylic acid (aspirin), COX = cyclooxygenase, 15-EpiLXA$_4$ = 15-epilipoxin A_4, HETE = hydroxyeicosatetraenoic acid, HPETE = hydroperoxyeicosatetraenoic acid, LT = leukotriene, LXA_4 = lipoxin A_4, LO = lipoxygenase, FLAP = 5-lipoxygenase activating protein, NSAID = nonsteroidal anti-inflammatory drug, PG = prostaglandin, TXA_2 = thromboxane A_2.

Aspirin-exacerbated respiratory disease is characterized by increased production of cysteinyl leukotrienes (CysLTs; leukotrienes C_4, D_4, and E_4) and eosinophilic infiltration.[72,134] Cys-LTs are metabolic products of phospholipid metabolism. Once phospholipid is liberated from the nuclear membrane, it is converted by phospholipase A_2 to arachidonic acid, which is then biotransformed into thromboxanes, prostaglandins, and 5-hydroperoxyeicosatetraenoic acid (5-HETE), which is ultimately biotransformed to leukotriene E_4 (LTE_4).[134,135] Cys-LTs are believed to be the primary mediators of AERD, as biosynthesis of Cys-LTs appears to be upregulated in AERD.[72] Cys-LTs are potent inflammatory mediators causing eosinophil chemotaxis, microvascular permeability, mucous-gland secretion, and bronchoconstriction.[136] Compared with eosinophils from aspirin-tolerant asthmatics, circulating blood eosinophils from patients with AERD carry larger amounts of leukotriene C_4 (LTC_4) synthase, the rate-limiting enzyme for Cys-LT production. Patients with AERD have a larger quantity of eosinophils in bronchial tissue compared to patients with aspirin-tolerant asthma, and Cys-LT concentrations in bronchial lavage fluids correlate with the degree of eosinophilic infiltration of bronchial tissue in patients with AERD.[137] In addition, LTC_4 synthase is overexpressed in the bronchial mucosa of patients with AERD.[137,138]

It is postulated that COX inhibition by aspirin and NSAIDs drives arachidonic acid through the leukotriene metabolic pathway.[139] COX exists in several isoforms, with COX-1 expressed constitutively in most tissues and COX-2 induced by inflammatory mediators.[140] COX enzymes metabolize arachidonic acid to the proinflammatory mediators prostaglandins D_2 (PGD_2) and $F_2\alpha$ ($PGF_2\alpha$), and the anti-inflammatory mediator prostaglandin E_2 (PGE_2).[141] Exposure to aspirin and most NSAIDs results in decreased production of COX metabolic products such as PGE_2, which normally inhibits 5-lipooxygenase (5-LO) and 5-LO activating protein (FLAP). The “braking effects” of PGE_2 are greatly minimized, leaving 5-LO unopposed. This leads to oversynthesis of leukotrienes, a reduction in mast-cell stabilization, and the release of histamine and tryptase.[140]

Both β_1 and β_2-adrenergic receptors are present in the heart and the lungs, but β_1-receptors are found primarily in the heart and β_2-receptors are mainly found in bronchial smooth muscle.[3] β-blockers competitively inhibit stimulation of β-adrenergic receptors, resulting in unopposed parasympathetic tone, which can result in bronchoconstriction.[3,23,142] Stimulation of β_2-receptors (as with β_2-receptor agonists) results in relaxation of bronchial smooth muscle, while blocking these receptors results in airway constriction.[22] It is important to consider all routes of administration of β-receptor active agents. Up to 80% of the volume of topically administered β-blocker eyedrops drains into the nasolacrimal duct and is absorbed via the nasal mucosa.[110] Nonselective β-receptor inhibition substantially shifts the dose–response curve of inhaled β_2-adrenergic agonists (β_2-agonists), limiting their effectiveness in reversing bronchospasm caused by nonselective β-blockers. Cardioselective β-blockers preferentially bind to β_1-adrenergic receptors, but this selectivity is attenuated at higher doses. Bronchospasm caused by cardioselective β-blockers may be easier to reverse with inhaled β_2-agonists.[143]

The mechanism of ACE-inhibitor–induced cough has not been clearly elucidated, although increased concentrations of proinflammatory substances like bradykinin, substance P, prostaglandins, and thromboxane are likely involved.[13]

ACE converts angiotensin I to angiotensin II and is also responsible for metabolism of bradykinin, substance P, and neurokinin A.[3] ACE-inhibitor–induced cough may result from the accumulation of these substances in the lungs. Bradykinin and substance P activate mast cells, releasing proinflammatory mediators. In addition, bradykinin is a vasodilator and increases vascular permeability. Inhaled bradykinin causes bronchospasm, possibly through increases in the production of thromboxane A_2, prostacyclin I_2 (PGI_2), and PGE_2, which can activate rapidly acting receptors of the afferent neuronal pathway, stimulating the cough reflex. The accumulation of substance P may also play a role in ACE-inhibitor–induced cough, as it serves as a neurotransmitter for the afferent neurons, in particular sensory C fibers, and can cause bronchoconstriction.[144] A genetic predisposition for ACE-inhibitor–induced cough may exist.[126]

Several different mechanisms may cause paradoxical bronchospasm, including turbulent airflow due to inappropriate inhaler use, the deep inspiratory maneuver used for drug inhalation, IgE-mediated reactions to product excipients (e.g., soy lecithin), excipients in metered-dose inhalers (e.g., oleic acid), and hyperosmolar or acidic nebulizer solutions.[46]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The signs and symptoms of drug-induced bronchospasm can be nonspecific and may be difficult to differentiate from other causes of bronchospasm, such as asthma and chronic obstructive pulmonary disease (COPD) (**Table 22-3**).[145,146] Conditions that should be considered in the differential diagnosis of drug-induced asthma or bronchospasm are listed in **Table 22-4**.[12,147] Recent drug exposure and the presence of other risk factors (**Table 22-5**) are usually required for the diagnosis.[3,14,16,129,148] When in doubt, specialists in clinics with the ability to treat anaphylactic reactions should challenge the patient with the suspected causative agent in a controlled environment.

Table 22-3 Signs and Symptoms Associated with Drug-Induced Asthma and Bronchospasm

Drug-induced asthma and bronchospasm[145]

- Tachypnea
- Tachycardia
- Wheezing
- Diaphoresis
- Cyanosis

- Dyspnea
- Cough
- Shortness of breath
- Chest tightness
- Anxiety
- Agitation

ACE-inhibitor–induced cough[146]

- Tickling sensation in the back of the throat
- Dry, hacking, irritating nonproductive, paroxysmal cough
- Hoarseness

ACE = angiotensin-converting enzyme.

Aspirin-exacerbated respiratory disease is an acquired condition that may develop as adult-onset asthma or be superimposed on pre-existing asthma. The typical presentation is that of the classic aspirin tetrad of rhinitis, nasal polyps, asthma, and aspirin intolerance. Typically, symptoms of chronic rhinitis present in the late teen years to middle age and often follow a viral infection.[127] Rhinitis usually worsens, becomes refractory to treatment, and progresses to chronic hyperplastic eosinophilic sinusitis with nasal polyposis.[72] Asthma may develop 1–5 years after the development of rhinitis with polyposis.[127] The development of aspirin or NSAID sensitivity can occur at any point during the disease. Most patients with AERD are not clinically distinguishable from aspirin-tolerant patients with asthma until challenged with aspirin/NSAIDs. Patients may have an acute asthma attack with symptoms of rhinorrhea and conjunctival infection within minutes to 3 hours of ingestion of aspirin or NSAIDs.[138] A small number of patients present with nonrespiratory symptoms such as urticaria or angioedema after aspirin ingestion.[72] Often, reactions are severe and can be life-threatening.

Table 22-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Asthma and Bronchospasm

Drug-induced asthma and bronchospasm[12]

- Pre-existing chronic asthma
- Pre-existing chronic obstructive pulmonary disease
- Allergic rhinitis and sinusitis
- Upper respiratory tract infection
- Foreign body in the trachea or bronchus
- Vocal cord dysfunction
- Vascular rings or laryngeal webs
- Laryngotracheomalacia, tracheal stenosis, bronchostenosis
- Laryngeal edema
- Viral bronchitis or obliterative bronchiolitis
- Cystic fibrosis
- Bronchopulmonary dysplasia

- Aspiration
- Gastroesophageal reflux
- Heart failure
- Pulmonary embolism
- Tumor causing mechanical obstruction
- Acute bronchitis
- Pulmonary infiltration with eosinophilia

ACE-inhibitor–induced cough[147]

- Upper respiratory tract infection
- Allergic rhinitis and sinusitis
- Asthma
- Chronic obstructive airway disease
- Gastroesophageal reflux
- Laryngitis
- Heart failure
- Mitral stenosis
- Pneumonia
- Pulmonary emboli
- Acute bronchitis
- Smoker's cough
- Tuberculosis
- Lung carcinoma

Table 22-5 Risk Factors for Drug-Induced Asthma and Bronchospasm

Aspirin-induced asthma[129]

- Pre-existing asthma
- Nasal polyps
- Age (30s or 40s)
- Female sex

β-blockers[3]

- Pre-existing airway hyperreactivity

ACE-inhibitor–induced cough[14,16,148]

- Female sex
- African-American or Asian race
- Elderly
- Heart failure
- Genetic polymorphism (bradykinin metabolism gene *XPNPEP*$_2$ and bradykinin receptor gene *BDKRB*$_2$)

ACE = angiotensin-converting enzyme.

Diagnosis of AERD begins with a detailed medical history. However, the history may not be helpful because the patient may have taken aspirin or NSAIDs successfully in the past, without bronchospasm or other adverse respiratory effects. Aspirin or NSAID-induced asthma should be suspected when symptoms of persistent and intractable rhinorrhea and nasal congestion occur after ingestion of aspirin or NSAIDs in patients with current nasal polyps or loss of smell and mucosal hypertrophy on CT scan. Patients with AERD tend to have more severe asthma symptoms with an increased risk of severe exacerbations. There is no in vitro test available for the diagnosis of AERD; the definitive diagnosis is made using aspirin provocation tests, during which aspirin may be administered by the oral, inhaled, nasal, or intravenous route (of these, only oral administration is available in the United States). Patients should be challenged when asthma is in remission with an FEV_1 >70% of the predicted value, and the provocation test should be carried out by specialists in clinics with immediate access to emergency equipment and ability to treat anaphylactic reactions. Discontinuation of asthma controller medications is not recommended, as it may lead to severe reactions.[72]

In an oral provocation test, the patient receives placebo capsules the day prior to the challenge to allow for estimation of bronchial stability. On day 2, patients receive 10–30 mg of aspirin, and the dose is doubled every 1.5–3 hours until a positive reaction (nasal congestion, rhinorrhea, or at least a 20% decrease in FEV_1) occurs. If the final aspirin dose is 312 mg (equivalent to 500-mg cumulative dose) and well tolerated, the patient is considered aspirin tolerant.[72] A nasal provocation test involves the administration of lysine-aspirin 8 mg into each nostril (total dose, 16 mg) with rhinomanometry performed every 10 minutes for 2–3 hours.[149] A positive test is defined as a decrease in nasal flow of >40% compared with baseline in at least one nostril that is sustained for at least two rhinomanometry measurements and is accompanied by clinical symptoms persisting for ≥30 minutes.[150,151] During oral inhaled provocation tests, an inhalation of normal saline is administered, and if FEV_1 does not decrease by >10%, increasing oral inhaled doses of lysine aspirin are given every 30 minutes to a maximum cumulative dose of 182 mg. Spirometry is performed at 10, 20, and 30 minutes after each dose. A decrease in FEV_1 of >20% from baseline or the occurrence of substantial extrabronchial symptoms is considered positive for aspirin-induced asthma. Bronchial provocation with lysine-aspirin is as sensitive as, but less specific than, oral provocation testing.[152] The oral route is generally recommended over both intranasal and inhaled routes for the provocation test. Patients with significant nasal obstruction or turbulent nasal flow should not be administered intranasal aspirin. Similarly, those with chronic rhinosinusitis without asthma or those with a history of only upper airway symptoms after NSAID ingestion cannot undergo the inhaled challenge.[72]

Bronchospasm due to β-blockade cannot be distinguished clinically from an acute asthma attack. Drug-induced bronchospasm should be suspected in any asthmatic patient who wheezes while taking a β-blocker. A single dose of a cardioselective β-blocker can result in a significant decrease in FEV_1, whereas chronic β-blocker administration may not cause a significant reduction in FEV_1.[153]

ACE-inhibitor–induced cough is typically characterized as dry, irritating, and nonproductive with a persistent tickling sensation in the back of the throat.[146,154] The cough may present within hours of the first dose, or it may be delayed up to 12 months after the initiation of therapy. ACE-inhibitor–induced cough may cause hoarseness, vomiting, and stress incontinence, and the cough may worsen in the supine position or at night.[147,155] Although the cough may resolve within a week after the discontinuation of ACE-inhibitor therapy, it may linger for 1–3 months in some individuals.[147,154] The differential diagnosis of ACE-inhibitor–induced cough includes asthma, chronic smoking, COPD, postnasal drip, heart failure, upper-respiratory-tract infection, and gastroesophageal reflux.[147,155,156] Diagnosis of ACE-inhibitor–induced cough requires discontinuation of therapy and monitoring of the cough. Diagnosis is confirmed by resolution of the cough within 1–4 weeks after discontinuation, although, as mentioned above, in a subgroup of patients the cough may last up to 3 months.[154]

Patients with paradoxical responses to inhaled drugs demonstrate a lower-than-expected response to the drug or worsening of their pulmonary symptoms. The response is usually rapid and may occur within minutes of inhaling the agent.[157] Patients with known severe asthma have often reported severe wheezing, chest tightness, and dyspnea after ingesting sulfite-containing foods. Reactions to sulfites rarely occur in patients without reactive airway disease. The diagnosis of sulfite sensitivity is made by taking a detailed history and may be confirmed by rechallenge.[119]

RISK FACTORS

Risk factors for drug-induced asthma and bronchospasm are listed in Table 22-5. The principal risk factor for drug-induced bronchospasm is pre-existing asthma. However, smoking, pre-existing airway disease, older age, and respiratory infection may also increase the risk for drug-induced bronchospasm.[4]

Aspirin-exacerbated respiratory disease occurs primarily in adults and generally does not manifest until the 30s or 40s.[129] The frequency of AERD increases with age, and the incidence is fourfold higher in patients 40 years of age or older compared with those younger than 20 years.[2] The risk of AERD also increases with a patient's asthma severity; the prevalence is doubled in patients with severe persistent asthma.[17] Women are affected 2–2.5 times more often than men.[18,158,159] In a study of 500 aspirin-intolerant asthmatic patients from 10 European countries, the prevalence of AERD was 2.3 times greater in women than in men. In women, the onset of symptoms occurred earlier in life, and the disease was more progressive and severe.[158] A study of 300 patients in the United States found the prevalence of AERD to be only 1.3 times greater in women than in men, and the severity of the disease was similar in both sexes.[160] There appears to be no ethnic or familial distribution of AERD, with only 6% of patients in the European study and 1% in the U.S. study having a family history of AERD.[158,160] Patients with nasal polyps or chronic rhinosinusitis had a 9.69% prevalence and 8.7% prevalence, respectively.[17]

ACE-inhibitor–induced cough occurs more often in female patients, in those of Chinese origin, and in nonsmokers.[126,154,161,162] ACE-inhibitor–induced cough is not dose-related and can occur in patients taking initial starting doses.[147] Patients with chronic lung diseases such as COPD or asthma do not appear to be at a greater risk for cough associated with ACE inhibitors.[163] Patients with heart failure that are treated with an ACE inhibitor have a higher incidence of cough than those treated with ACE inhibitors for hypertension.[154] There is speculation regarding the potential for a genetic predisposition to ACE-inhibitor–induced cough. Some evidence implicates polymorphisms in the bradykinin metabolism gene ($XPNPEP_2$) and bradykinin receptor genes ($BDKRB_2$).[148]

MORBIDITY AND MORTALITY

Any drug reaction that causes acute bronchospasm or exacerbates asthma has the potential to negatively impact patient morbidity and mortality. In patients with AERD, who tend to have more severe asthma, aspirin therapy may be associated with aggressive airway remodeling and, in some, decreased diffusion capacity. A study evaluating factors associated with the development of severe asthma found that 9.44% of patients had experienced aspirin intolerance; of those, 30.67% had severe asthma. Aspirin was a significant risk factor for the development of severe asthma (OR 5.44, 95% CI 2.47–8.41).[164] Another study evaluating 3,307 adult patients with severe or difficult-to-treat asthma demonstrated that the mean percent predicted postbronchodilator FEV_1 was significantly decreased in those who were aspirin-intolerant (75.3%) as compared with those who were aspirin-tolerant (79.9%), and patients with aspirin-intolerant asthma were more likely to have severe asthma based on physician assessment (66% versus 49%).[165] A greater percentage of aspirin-intolerant subjects had a history of intubation (20% versus 11%), and over a 3-month period had more unscheduled office visits (54% versus 44%), emergency department visits (18% versus 13%), and requirement for burst doses of steroids (56% versus 46%).[165] A survey of 500 patients with AERD in 10 European countries found that inhaled and oral corticosteroids were required in 80% and 50% of patients, respectively. The average corticosteroid dose was equivalent to prednisone 8 mg daily.[158] NSAID exposure has also been shown to be a risk factor for rapid-onset fatal or near-fatal asthma.[166]

The responses to a survey administered to 200 patients with AERD indicated that it can also influence quality of life. When asked how badly AERD affected their lives, with a score of one representing mild and score of nine representing severe, most respondents ranked their quality of life with a score of seven. The two categories that diminished quality of life most severely were decreased sense of smell (89%) and chronic nasal symptoms (87%).[167]

The risk of increased morbidity and mortality due to β-blocker-induced bronchospasm is unknown, but fatalities due to bronchospasm caused by these agents have occurred. Single-dose exposure to selective β-blockers can cause a mean decrease in FEV_1 of 7.46% with no change in symptoms.[153] In a meta-analysis of randomized controlled trials evaluating acute nonselective β-blocker exposure in patients with asthma, there was a mean change in FEV_1 of −10.2% and symptoms affecting one in 13 patients. In patients with asthma exposed to acute selective β-blocker therapy, there was a mean change in FEV_1 of −6.9% and symptoms affecting 1 in 33 patients. This meta-analysis also showed an attenuation of concomitant β_2-agonist response of −10.2% in patients exposed to acute selective β-blocker therapy and −20% in patients exposed to acute nonselective β-blocker therapy.[23] Although bronchoconstriction may occur after a single dose of a β-blocker, some researchers suggest that β-blockers may have a beneficial effect for patients with asthma. In one small study, including patients with mild asthma, the nonselective β-blocker nadolol exerted a dose-dependent and significant attenuation in airway hyperresponsiveness from baseline in 80% of the patients.[168]

The largest impact of the persistent cough associated with ACE inhibitors is the potential for patient self-discontinuation of therapy. Discontinuation rates as high as 50% have been reported.[147] The chronic, bothersome cough may also decrease quality of life and potentially increase the use of healthcare resources to determine cough etiology.[147] Patients may also seek nonprescription or prescription medication to relieve the cough.[169]

The morbidity and mortality associated with paradoxical bronchospasm is unknown. However, an ineffective or worsening response from a bronchodilator during an active asthma attack could lead to significant morbidity.

PREVENTION

The primary strategy for preventing drug-induced asthma or bronchospasm is avoidance of causative agents (**Table 22-6**). Alternative analgesic treatments for patients with AERD include acetaminophen, salsalate, meloxicam, and celecoxib.[138] Cases of successful use of COX-2 inhibitors have been reported.[170] However, there have also been reports of COX-2 inhibitors inducing bronchospasm.[171,172] Eight combined studies (n = 206) demonstrated that COX-2–selective NSAIDs may be used safely in patients with AERD.[173] Aspirin-induced asthma is not a risk factor for mortality if aspirin and NSAID avoidance is ensured.[174]

Table 22-6 Approaches to Help Prevent Drug-Induced Asthma and Bronchospasm

Drug	Condition	Prevention
Aspirin	Asthma	Avoidance of aspirin Aspirin desensitization Acetaminophen, salsalate, meloxicam, or celecoxib may be used instead of aspirin
β-blockers	Bronchospasm	Use cardioselective β-blockers at lowest possible dose
ACE inhibitors	Cough	Avoidance of ACE inhibitors Use angiotensin receptor blocker or antihypertensive agent from a different class

ACE = angiotensin-converting enzyme.

The frequency of cross-sensitivity between aspirin and acetaminophen is uncertain, but is likely between 0 and 6%. Studies show that patients with AERD can usually tolerate single acetaminophen doses of up to 650 mg safely. Single doses of 1,000 mg, however, induce bronchospasm in up to 20% of patients. These reactions associated with acetaminophen tend to be less severe than those associated with aspirin.[73] Aspirin desensitization is a possible alternative if avoidance of aspirin, aspirin-containing products, or NSAIDs is not possible in patients with AERD. Aspirin desensitization, a process involving repeated exposure to aspirin in increasing doses to eliminate adverse effects related to its use, allows patients to take aspirin or cross-reacting NSAIDs. Desensitization and daily aspirin use can significantly improve patient symptoms and quality of life, decrease nasal polyps, and reduce the need for oral corticosteroids and sinus surgery. Desensitization also has been shown to improve nasal and asthma symptom scores in patients with AERD. Contraindications to desensitization include pregnancy, unstable asthma, gastric ulcers, and bleeding disorders. Numerous aspirin desensitization protocols exist. One such protocol desensitizes patients over several days. Patients should have a baseline FEV_1 ≥60% predicted (at least 1.5 L). Therapy with a leukotriene modifier should be initiated if one is not currently taken, and patients should continue therapy with oral or inhaled corticosteroids and long-acting bronchodilators. Antihistamines and short-acting β-agonists should be held prior to the challenge. The protocol starts with administration of aspirin 20–40 mg every 3 hours. If a reaction occurs, it is treated before continuing. This initial provocation dose is then repeated. The effects of aspirin desensitization last indefinitely, but long-term therapy is necessary to maintain desensitization. Maintenance treatment with aspirin should be at least 325 mg and ideally twice daily to ensure adequate anti-inflammatory activity in the respiratory tract. For patients who need primary cardiovascular prophylaxis with aspirin, 81-mg doses may maintain the desensitized state.[175]

Because of the mortality benefits demonstrated with β-blockers, their use may be necessary in patients with HFrEF and/or a history of myocardial infarction.[143] Nonselective β-blockers are contraindicated in patients with asthma. However, one meta-analysis concluded that β_1-selective β-blockers should not be avoided in patients who may benefit from their use.[153] Reports of bronchospasm with low doses and β_2-receptor blockade associated with high doses of cardioselective β-blockers have been documented. Therefore, the chosen cardioselective β-blocker should have a short half-life and be initiated at the lowest possible dose, and upward dose titration should occur slowly.[143] Although cardioselective β-blockers are associated with a lower incidence of respiratory adverse effects than nonselective β-blockers, both types should be avoided in patients with severe asthma. Patients requiring therapy with a topical ophthalmic β-blocker to decrease intraocular pressure should also be prescribed a cardioselective agent such as betaxolol.[143]

MANAGEMENT

Based on one of the proposed mechanisms of AERD, both cys-LT_1 receptor antagonists (zafirlukast and montelukast) and 5-lipoxygenase inhibitors (zileuton) should play a role in the management of AERD.[173,176] A study involving 46 patients evaluated the impact of long-term montelukast therapy in protecting against AERD in aspirin-intolerant patients. Patients with mild or moderate asthma received montelukast 10 mg daily for 12 weeks. The decline in FEV_1 following aspirin challenge decreased from 28.6% ± 1.9% to 10.2% ± 1.7% ($p = 0.0001$). Patients were were considered poor responders if they demonstrated >15% decline in FEV_1 after aspirin challenge. Poor responders ($n = 14$, 30%) had a higher incidence of rhinosinusitis, history of aspirin hypersensitivity, and larger decline in FEV_1 following aspirin challenge before treatment compared with good responders (37.6% ± 3.8% versus 24.7% ± 1.8%; $p = 0.005$).[177]

Numerous smaller studies have evaluated the impact of zileuton in patients with AERD. In one study, $n = 7$ patients demonstrated a mean maximal decrease in FEV_1 of 2.9% while taking with zileuton compared with 4.9% during placebo after an aspirin challenge. However, only two patients in the study experienced complete inhibition of aspirin-induced respiratory adverse effects.[178] Another small study (*n* = 6) evaluated the effect of zileuton and placebo before and during an aspirin challenge. The mean aspirin dose provoking a respiratory reaction was 57 mg (30–100 mg) during initial challenge and increased to 122 mg (45–325 mg) in patients taking zileuton 600 mg four times daily. No participants could tolerate typical aspirin doses, and the authors concluded that the dose of zileuton was inadequate in preventing aspirin-induced respiratory reactions.[179] A study of similar design (*n* = 8) demonstrated much different results with zileuton, showing decreased urinary LTE_4 excretion and a FEV_1 decrease of 4.4% associated with zileuton, compared with 18.6% during placebo.[180] Differences between the studies may be due to differences in zileuton doses. One study used escalating doses of zileuton, whereas the other used a previously determined threshold dose. Differences between the studies may also be related to differences in the patients' disease severity.[181] Patients taking a 5-lipoxygenase inhibitor or a Cys-LT_1 receptor antagonist should continue to exercise caution with aspirin, NSAIDs, and other cross-reacting agents, because bronchospasm may occur.[173]

Omalizumab was shown to facilitate aspirin desensitization in a case report. A patient who had been previously unresponsive to aspirin desensitization received 16 weeks of omalizumab therapy (four doses), after which she underwent 10 days of aspirin desensitization, resulting in aspirin tolerance. Two years later the patient was still able to tolerate aspirin 600 mg daily, did not require asthma control treatment, did not have urticaria, and denied nasal polyp recurrences.[182] The biologic agent mepolizumab, which targets eosinophils, may also have potential for the management of AERD.

A survey of patients with a diagnosis of AERD reported that 88% of patients had been treated with a leukotriene-modifier agent, 24% underwent a trial of zileuton therapy, and 8% had been treated with omalizumab. The greatest benefit was associated with leukotriene receptor antagonists, with 50% of patients remaining on chronic leukotriene receptor antagonist therapy for AERD.[167]

Ipratropium is the preferred treatment for β-blocker–induced bronchospasm.[2] Oxitropium, an antimuscarinic, has also been shown to prevent acute propranolol-induced bronchoconstriction.[183] In addition, evidence has shown that tiotropium may prevent propranolol-induced bronchoconstriction after acute dosing during up-titration to 80 mg. There was no significant difference observed in methacholine or histamine airway hyperresponsiveness for patients receiving propranolol or placebo and no adverse impact on asthma control. Albuterol may be used to treat β-blocker–induced bronchospasm, but acute effects may be attenuated. In one study, after methacholine challenge, patients received albuterol and ipratropium. There was a significant decrease in area under the curve for patients treated with propranolol versus placebo; however, after 20 minutes the difference was no longer significant.[184]

Once ACE-inhibitor–induced cough is suspected, the drug should be discontinued to determine whether the cough is ACE-inhibitor–induced.[147]The cough usually resolves within 1–4 weeks but may take up to 3 months in some individuals.[147,154] A rechallenege may be performed with the same or a different agent to determine if cough recurs. In some patients the cough may abate with long-term therapy or subside spontaneously.[147] Alternatives to ACE inhibitor therapy include ARBs or antihypertensive agents from different drug classes. ARBs are effective for the management of hypertension or heart failure but do not directly inhibit ACE activity or inhibit bradykinin metabolism. Randomized, controlled studies of ARBs have demonstrated a lower incidence of cough in patients with a history of ACE-inhibitor–induced cough.[185,186] In one meta-analysis of studies conducted in patients with intolerance to ACE inhibitors, the incidence of cough associated with ARBs was 24%, compared with 67% associated with ACE inhibitors.[187] If a patient with ACE-inhibitor–induced cough must remain on ACE inhibitor therapy, there are limited drug therapy options to manage cough. Drug therapy, including inhaled cromolyn, theophylline, sulindac, indomethacin, amlodipine, nifedipine, ferrous sulfate, and picotamide (not available in the United States) has been reported to exert some beneficial effects on ACE-inhibitor–induced cough in small, randomized, double-blind, placebo-controlled trials. Small, unblinded, uncontrolled studies have provided limited evidence supporting the use of baclofen, ozagrel, and aspirin (500 mg/day) for management of ACE-inhibitor–induced cough. After discontinuation of the ACE inhibitor and resolution of the cough, a repeat trial of an ACE inhibitor may be attempted in patients with a compelling reason to use an ACE inhibitor and who are unable to take an ARB.[154] Some evidence suggests that ACE-inhibitor–induced cough occurs less frequency with concomitant calcium channel blocker or diuretic therapy compared to that associated with ACE inhibitor monotherapy. There was also a lower frequency of cough when the ACE inhibitor was taken at bedtime.[188]

INFORMATION FOR PATIENTS

Patients with AERD should be instructed to avoid potent COX-1 inhibitors such as aspirin, ibuprofen, ketoprofen, and others. Weak peripheral inhibitors of COX-1 and COX-2 (e.g., acetaminophen, salsalate) may be used, but patients should be informed that there is a chance of exacerbation of asthma with these drugs and to immediately discontinue therapy if this is suspected.[1,3,172,173] Aspirin or NSAID allergy must be documented in all medical records, including at the patient’s pharmacy. Patients should be instructed to consult their pharmacist to select nonprescription products with no cross-reactivity with aspirin. Because cross-reactivity is dose-related for some medications, patients should be advised to take only doses recommended by a healthcare provider.

Patients with a respiratory condition such as asthma or COPD should inform providers of their condition. If a patient is prescribed a β-blocker, the patient should be instructed not to take more than the prescribed dose. It is necessary for patients taking β-blockers to inform healthcare providers about their use and be warned that they may exacerbate respiratory conditions.

If patients experience cough due to ACE inhibitors, they should be instructed to contact their healthcare provider and not to treat the cough with nonprescription products. ACE-inhibitor–induced cough is treated with antitussive therapy in approximately 15% of all cases.[189] In one study, treatment with prescription antitussive therapy was twice as likely in patients taking ACE inhibitors compared to patients who did not receive ACE inhibitor therapy. This study did not assess the use of nonprescription antitussives, which would likely increase the risk of misdiagnosis and mistreatment of ACE-inhibitor–induced cough.[169] Patients using ACE inhibitors who experience a chronic cough should be referred to their medical provider to determine the etiology.

Myocardial Ischemia and Acute Coronary Syndromes

Kevin M. Sowinski

Myocardial ischemia occurs as a result of increased myocardial demand, decreased myocardial oxygen supply, or both, and most commonly occurs in patients with atherosclerotic coronary artery disease. This chapter discusses the specific mechanisms by which drug therapy may cause increased myocardial oxygen demand or decreased supply.

Angina pectoris is a clinical syndrome of chest discomfort caused by reversible myocardial ischemia that produces disturbances in myocardial function but no myocardial necrosis. Myocardial ischemia can also occur without any symptoms of angina and is typically referred to as silent myocardial ischemia. Acute myocardial infarction (MI) is a clinical syndrome associated with the development of a prolonged occlusion of a coronary artery leading to decreased oxygen supply, myocardial ischemia, and irreversible damage to myocardial tissue. MI in patients with coronary artery disease is usually associated with a coronary artery thrombosis superimposed on a ruptured atherosclerotic plaque. The specific mechanisms by which drugs may facilitate or cause MIs will be discussed.

An acute coronary syndrome is associated with three clinical manifestations: ST-segment elevation MI, non-ST-segment elevation MI, and unstable angina.[1,2] For the purposes of this chapter, it is difficult to separate the acute coronary syndromes because, for the most part, the individual case data in the literature do not provide sufficient detail. Therefore, in most cases, the specific acute coronary syndromes will not be discussed separately. Furthermore, based on the available literature, it is difficult to distinguish drugs based on whether they cause myocardial ischemia or infarction.

CAUSATIVE AGENTS

Drugs reported to cause angina pectoris, myocardial ischemia, an acute coronary syndrome, or all three are listed in **Table 23-1**.[3-462] Drug-induced myocardial ischemia or acute coronary syndrome can occur in association with short-term drug administration or during long-term therapy. Because of the temporal nature of case reporting of these drug-induced diseases, in most cases the chapter will review drugs that cause myocardial ischemia or infarction acutely. In some cases, larger and longer-term clinical trials or epidemiologic evidence support a relationship between the development of myocardial ischemia or infarction and long-term administration of a drug. Chronic use of drugs such as cocaine, oral contraceptives, nicotine, rosiglitazone, protease inhibitors, selective cyclooxygenase-2 (COX-2) inhibitors and nonselective nonsteroidal anti-inflammatory drugs (NSAIDs), and others may facilitate or increase the risk of atherosclerotic coronary artery disease and associated myocardial ischemia and infarction. This phenomenon may be thought of as analogous to other factors that increase the risk of coronary artery disease (such as hypertension, diabetes mellitus, obesity, and others). This subject area has received considerable attention from the media, patients, and regulatory agencies because of studies suggesting an increased risk of cardiovascular disease associated with selective COX-2 inhibitors and nonselective NSAIDs.[7,18-22,27,463] Finally, drugs may cause myocardial ischemia or acute coronary syndrome if therapy is abruptly discontinued.

Table 23-1 Agents Implicated in Drug-Induced Myocardial Ischemia and/or Acute Coronary Syndromes

Therapeutic Area (drug class, drugs)	Incidence/Index of Risk	Level of Evidence[a]
Drug Discontinuation[3-16] Argatroban, aspirin, β-blockers, clonidine, clopidogrel, heparin, nitroglycerin	NK	C

Analgesics[7,17-28]		
NSAIDs	Highly variable, dependent on drug and drug dose	A, B, C
Selective COX-2 inhibitors (rofecoxib, celecoxib, valdecoxib)	Celecoxib: RR 1.86, 95% CI 1.33–2.54	
Nonselective NSAIDs (diclofenac, ibuprofen)	Ibuprofen: RR 1.51, 95% CI 0.96–2.37	
	Diclofenac: RR 1.63, 95% CI 1.12–2.37	
Opioids (methadone, dihydrocodeine, morphine)	NK	C
Others (ketamine, gold sodium thiomalate, nefopam, penicillamine)	NK	C
Anesthetics[29-32] Benzocaine, enflurane, isoflurane, mepivacaine, sevoflurane, propofol	NK	C
Anticancer/Cancer-Associated Agents[33-112] 5-fluorouracil, bleomycin, capecitabine, carboplatin, carmustine, cisplatin, cyclophosphamide, epirubicin, etoposide, gemcitabine, hydroxyurea, floxuridine, flutamide, L-asparaginase, lapatinib, ixabepilone, methotrexate, paclitaxel, sorafenib, vinblastine, vincristine, vinorelbine	NK	C
Antidepressants[17,113-123] Selective serotonin reuptake inhibitors (fluvoxamine, fluoxetine, sertraline, venlafaxine) Tricyclic antidepressants Others (bupropion, doxepin, maprotiline, trazodone, phenelzine)	NK	C
Anti-HIV[124-131]		
Abacavir, didanosine	Abacavir: RR 1.89, 95% CI 1.47–2.45	B
	Didanosine: RR 1.49, 95% CI 1.14–1.95	B
Protease inhibitors	Protease inhibitors: RR 1.16, 95% CI 1.10–1.23	B
Anti-Infectives[17,132-139] Amoxicillin, amphotericin, azithromycin, cinoxacin, clarithromycin, co-trimoxazole, fluconazole, ketoconazole, mefloquine, mesalamine, metronidazole, nitrofurantoin, norfloxacin, penicillin G, roxithromycin	NK	C
Antipsychotics[17,120,140,141]	NK	C

Clozapine		
Antimigraine[17,142-176] Dihydroergotamine, ergonovine, ergotamine, methylergonovine, methylergometrine, methysergide, sumatriptan, zolmitriptan	NK	C
Blood Modifiers[17,177-181] Coagulation factor VIIA, darbepoetin, erythropoietin, factor VIII inhibitor/prothrombin complex concentrates, tranexamic acid	NK	C
Cardiovascular Drugs		
Calcium-channel blockers[17,182-207] (diltiazem, lacidipine, felodipine, isradipine, nifedipine, nisoldipine, verapamil)	NK	C
ACE inhibitors[17,208,209] (captopril, enalapril, lisinopril, perindopril)	NK	C
β-adrenergic blockers[17,198,201,210-213] (ophthalmic and systemic)	NK	C
Stress testing agents/β-adrenergic receptor agonists[214-237] (adenosine, arbutamine, atropine, dipyridamole, dopexamine, dobutamine, milrinone)	NK	C
Other cardiovascular drugs[17,238-244] (alfuzosin, diazoxide, disopyramide, diuretics, encainide, fenoldopam, hydralazine, levosimendan, minoxidil, nitroprusside, prazosin, propafenone, sublingual isosorbide dinitrate)	NK	C
Hormones/Hormone Modifying Agents[17,139,245-289]		
Female sex hormones (oral contraceptives, estrogens)	0- to 5-fold increase in risk (the risk is highly variable, dose and drug specific)	A, B, C
Other hormones (desmopressin, leuprolide, megestrol acetate, oxytocin, oral corticosteroids, prostaglandin F_2 [dinoprost], prostaglandin E_2 [sulprostone], tamoxifen, testosterone, thyroid hormone, vasopressin)	NK	C
Illicit Drugs[17,26,142,290-359]		
Amphetamines (methamphetamine, dextroamphetamine, 3,4-methylene-dioxymethamphetamine, dexfenfluramine)	NK	C
Cocaine	MI: 0.7–6% Chest pain: 39.4% NK	A, B, C C

Others (anabolic steroids, butane inhalation, glue sniffing, LSD, marijuana, heroin, cannabinoids, toluene inhalation)		
Immune Modulators[360-364] Interferon (alpha-2b), interleukins (alpha-2 and alpha-4), IVIG, smallpox vaccine, rituximab	NK	C
Sympathomimetics[17,116,316,328,365-395] Albuterol, ephedra, ephedrine, epinephrine, formoterol, isoproterenol, methylphenidate, pseudoephedrine, phenylephrine, phenylpropanolamine, salbutamol, salmeterol, sibutramine, terbutaline	NK	C
Other[36,124-126,139,142,350,396-462]	NK	C
Acetylcholine, allopurinol, azaribine, betamethasone, beclomethasone, bromocriptine, caffeine, capsaicin, cetirizine, cimetidine, cisapride, domperidone, dolasetron, ethanol, iloprost, ioversol, metoclopramide, lithium, nicotine, ondansetron, rosiglitazone, sildenafil, terfenadine, theophylline, tegaserod, varenicline	Rosiglitazone: OR 1.43, 95% CI 1.03–1.98	B

ACE = angiotensin-converting enzyme, CI = confidence interval, COX = cyclooxygenase, HIV = human immunodeficiency virus, IVIG = intravenous immunoglobulin, LSD = lysergic acid diethylamide, MI = myocardial infarction, NSAID = nonsteroidal anti-inflammatory drug, NK = not known, OR = odds ratio, RR = relative risk.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Data regarding drugs that may cause myocardial ischemia or infarction were summarized in a paper describing 20 years of reports (1975–1994) to a Netherlands national center for adverse drug reporting.[17] During this period, 19,141 adverse drug reactions were reported, of which 220 described likely cases of drug-induced chest pain or MI. The article describes 183 cases for which sufficient data were provided to evaluate the cases and adjudicate the findings. Data obtained from spontaneous reporting systems such as that in this article or from reports to the U.S. Food and Drug Administration (FDA) must be interpreted cautiously, as they typically suffer from both underreporting and/or selective reporting. Of particular note in this article is the absence of several classes of drugs or drug classes that are well known to cause myocardial ischemia or infarction, specifically cocaine and cytotoxic drugs. In addition, the underlying diseases of those patients for which adverse drug reactions were reported are not described.

Two recent papers have attempted to determine those at risk for drug-induced acute coronary syndromes and/or myocardial ischemia using two different methods. The first study used computer-based modeling to make predictions regarding protein targets that may be associated with the development of drug-induced MI.[464] The second utilized electronic health record databases in three countries—Denmark, Italy, and the Netherlands—to identify potential drugs that may cause drug-induced MI. The approach in this paper was to first detect potential drug-induced MI and then to identify whether the identified potential offending agent had been reported to cause this in the past. Based on available data, the authors then addressed the biological plausibility.[139] Initially, 163 drugs were identified as being associated with increased risk of MI. After eliminating drugs due to bias and lack of biological plausibility, only nine "prime suspects" were identified: azithromycin, erythromycin, roxithromycin, metoclopramide, cisapride, domperidone, betamethasone, fluconazole, and megestrol acetate (Table 23-1).

EPIDEMIOLOGY

The incidence of drug-induced myocardial ischemia and acute coronary syndromes in the general population is unknown and, with the exception of a small number of drugs, nearly impossible to determine. Nonetheless, drug-induced acute coronary syndrome and myocardial ischemia are not trivial. Both chest pain and MI were among the most common adverse events with serious outcomes reported to the FDA's voluntary reporting system between 1969 and 2002.[465] Although these reporting systems are flawed for the reasons discussed previously, they nevertheless suggest that drug-induced myocardial ischemia and acute coronary syndromes are a common and important problem. Due to the nature of these reports, the underlying conditions of the patients cannot be determined.

With the exception of certain groups (e.g., cocaine users, patients with chronic coronary artery disease, or those at high risk for coronary events) the incidence of drug-induced acute coronary syndromes and myocardial ischemia is likely low. However, several drugs/drug classes, including cocaine, oral contraceptives/hormone-replacement therapy, cytotoxic agents, ergot alkaloids, and triptans, may cause myocardial ischemia or acute coronary syndromes in individuals who do not have clinically evident cardiovascular disease.[323] To put into perspective the difficulty of determining the incidence of drug-induced myocardial ischemia and acute coronary syndromes, it is helpful to review the epidemiology of myocardial ischemia and acute coronary syndromes associated with cocaine and oral contraceptives, the drugs for which the most data are available. The risk of cocaine-induced MI is estimated to be 24–31 times greater than the baseline risk during the first hour after cocaine exposure.[319,320,324] The reported lifetime risk of acute MI in chronic cocaine users is six to seven times greater than that in nonusers. In view of the fact that 25 million Americans have used cocaine at least once in their lifetime, cocaine-induced myocardial ischemia/infarction has the potential to be a major public health problem. In 2011, 505,224 emergency department visits were cocaine-related.[466] Estimates suggest that as many as 40% of these emergency department visits included patients with chest discomfort. In patients whose urine is tested, cocaine or cocaine metabolites are detectable in 14–25% and 7% of those presenting to the emergency department with nontraumatic chest pain in urban and suburban hospitals, respectively. Although these data do not provide the actual incidence of chest pain or acute coronary syndrome associated with cocaine, they do provide some alarming information regarding the epidemiology and potential impact of this drug-induced disease.[319,320,322,324] The actual incidence of cocaine-induced MI among patients who present to the emergency department with cocaine-induced chest pain is highly variable, but ranges between 0.7% and 6%.[467-472]

Soon after oral contraceptives became available in the early 1960s, the first case report of MI associated with these drugs was published.[473] Since then, controversy regarding the potential for myocardial ischemia/infarction induced by oral contraceptives and other female hormones has lingered. Because exogenous female hormones (i.e., oral contraceptives and hormone-replacement therapy) are used by millions of women worldwide, the importance of the potential for myocardial ischemia or acute coronary syndromes associated with these agents is clear. Usually, oral contraceptives are taken by otherwise healthy young women with a low background risk of coronary artery disease and resulting myocardial ischemia or acute coronary syndromes. Numerous studies have been conducted to determine the risk of an acute coronary syndrome or other coronary event associated with oral contraceptive drugs, but the risk remains poorly defined. Depending on the study, type and dose of oral contraceptive used, and population studied, the degree of increased risk of myocardial ischemia/infarction associated with oral contraceptives varies widely, from no increased risk to a fivefold higher risk.[286,473] The hazard increases in women who smoke, have hypertension, diabetes, dyslipidemia, or are over the age of 35 years.[286,473] The effect of hormone-replacement therapy on the risk of coronary events is more strongly established. Numerous studies have called into question the safety of hormone-replacement therapy for reducing the risk of primary or secondary coronary events.[474,475] In January 2003, the FDA approved new labeling for all estrogen and estrogen/progesterone products, highlighting “the increased risk for heart disease, heart attacks” and that “these products are not approved for heart disease prevention.”[476]

Selective COX-2 inhibitors were introduced into the U.S. market in the late 1990s, with the potential to revolutionize the manner in which pain and inflammatory disorders were managed. However, several randomized active and placebo-controlled trials, observational studies, and meta-analyses have raised concerns that the selective COX-2 inhibitors and nonselective NSAIDs may increase the risk of MI.[7,18,463] Prospective well-designed studies comparing the effects of COX-2 inhibitors to those of other NSAIDs are not available, although until recently it was thought that nonselective NSAIDs did not increase cardiovascular risk. These trials have limitations, but it seems clear that there is an increase in risk associated with both selective and nonselective NSAIDs and that the risk is variable within each group of agents. The data suggest that the cardiovascular risk is highest with rofecoxib, followed by celecoxib and diclofenac, followed by naproxen and ibuprofen. Whether this is due to decreasing COX-2 selectivity from rofecoxib to ibuprofen is a topic of considerable debate.[22]

Two of the selective COX-2 inhibitors, rofecoxib and valdecoxib, were withdrawn voluntarily from the worldwide market in 2004 and 2005, respectively. "Black box" warnings for the remaining selective COX-2 inhibitor, celecoxib, and all other NSAIDs except aspirin were added to package inserts in 2006, stating: "NSAIDs may cause an increased risk of serious cardiovascular thrombotic events, MI, and stroke, which can be fatal. This risk may increase with duration of use. Patients with cardiovascular disease or risk factors for cardiovascular disease may be at greater risk." At the very least, these warnings should cause healthcare professionals to question the routine use of these agents in patients with cardiovascular disease. In 2013, the European Medicines Agency (EMA) further warned that diclofenac is associated with the same risk as the COX-2 selective inhibitors.[477] This warning was rendered in part due to the publication of a meta-analysis suggesting that COX-2 inhibitors and diclofenac increased vascular risk significantly, whereas ibuprofen and naproxen did not.[478] Subsequent papers suggest that this risk is increased regardless of the amount of time that has passed following an MI. Finally, a recent Danish registry study suggests that in post-MI patients receiving antithrombotic therapy, the risk of MI is independent of the type or duration of NSAID therapy.[479] In 2015, the EMA further warned that high-dose ibuprofen (>2,400 mg/day) was associated with a small increase in cardiovascular risk.[480] A scientific statement from the American Heart Association (AHA) with recommendations for the clinical use of these agents as well as numerous reviews and editorials expressing caution regarding the use of these drugs in patients with cardiovascular disease have been published.[478,479,481-484] Further research is needed in this area, but in the interim, cautious use of all NSAIDs is necessary, and the drugs should be used only in patients who understand the risk.

Two thiazolidinedione drugs, rosiglitazone and pioglitazone, are available for use in the United States for treating type 2 diabetes mellitus. Numerous meta-analyses and observational studies have reported an association between rosiglitazone and an increased risk of MI.[485] A randomized controlled trial designed to further investigate this association was not helpful in answering the important question due to design limitations. As a result of the increased risk of MI suggested by these studies, the FDA issued new prescribing information regarding the potential risk of rosiglitazone-associated myocardial ischemia, particularly in patients taking concomitant nitrate therapy, and instituted a highly restrictive prescribing program in 2010.[485,486] In 2011, the EMA went further and suspended the sale of rosiglitazone. The concerns have led to a scientific statement from the AHA/American College of Cardiology Foundation (ACCF) with recommendations for the clinical use of these agents.[485] Restrictions to the use of rosiglitazone were eased in 2013 based on an FDA advisory panel's recommendations. The FDA's action has met with conflicting opinions regarding the safety and appropriate use of rosiglitazone.[486] The majority of published studies do not suggest an increased risk of ischemic events associated with pioglitazone, and no black box warning is mandated for that drug.

The association between testosterone therapy and the risk of cardiovascular outcomes has been the focus of study recently, fueled by the marked increase in the use of testosterone therapy in men with low serum testosterone concentrations.[487-489] In response to several studies in which an association of increased cardiovascular risk was observed, the FDA issued warnings regarding the use of these products and concluded that despite conflicting and inconclusive evidence, there is the possibility that the testosterone increases cardiovascular risk. These studies were followed by intense media coverage and comment. The FDA mandated the addition of warnings regarding the possibility for increased risk of MI and stroke in patients taking these agents. The Endocrine Society issued a statement suggesting that, until randomized trials are available, patients should be aware of the potential increase in risk, and prescribers should use these agents in accordance with established treatment guidelines.[490] To date there are no large, long-term, randomized, placebo-controlled trials to provide definitive conclusions regarding testosterone therapy and cardiovascular risk. However, numerous smaller studies and a large meta-analysis argue that there is no increase in cardiovascular risk.[491] A published comprehensive literature review that assessed the available evidence concluded that there is no convincing relationship between testosterone therapy (for the treatment of low testosterone concentrations) and enhanced cardiovascular risk.[491]

MECHANISMS

Mechanisms of drug-induced myocardial ischemia and/or acute coronary syndromes are listed in **Table 23-2**.

DRUG-INDUCED MYOCARDIAL ISCHEMIA

Myocardial ischemia results from an imbalance in coronary blood flow, myocardial oxygen supply, and the metabolic needs of the myocardium (myocardial oxygen demand). Myocardial ischemia occurs when myocardial oxygen demand exceeds myocardial oxygen supply. The three major determinants of myocardial oxygen demand are heart rate, contractility, and left ventricular systolic wall tension.[492] Heart rate is the easiest of these factors to assess clinically; an increase in heart rate leads to increased myocardial oxygen demand. Myocardial contractility is reflected by the rate of rise in the intraventricular pressure during isovolumetric contraction and is influenced by a number of variables, including the autonomic nervous system, heart rate, blood calcium concentration, and body temperature. The third determinant, systolic wall tension, is directly related to ventricular systolic pressure and ventricular wall radius and is inversely related to wall thickness. Preload and afterload are important determinants of these components. Reducing systolic blood pressure reduces afterload, which ultimately decreases myocardial oxygen demand. A drug may cause myocardial ischemia simply by modifying any one of these factors. For example, drugs that increase heart rate, either directly (e.g., cocaine, β-adrenergic receptor agonists, abrupt discontinuation of β-blockers) or indirectly by reflex mechanisms (e.g., potent vasodilators such as nifedipine, minoxidil, and hydralazine) may induce myocardial ischemia. Similarly, drugs that increase systolic blood pressure (e.g., cocaine, phenylephrine) may also induce myocardial ischemia. Clinicians should be aware of drugs that modify any of these factors, as they may cause myocardial ischemia.

Table 23-2 Mechanisms of Drug-Induced Myocardial Ischemia and/or Acute Coronary Syndrome

Drug-Induced Disease and Mechanism	**Examples** (This is a partial list of examples only; for most drugs the mechanism of increased risk is not known.)
Drug-Induced Myocardial Ischemia	
Increased myocardial oxygen demand	
Increased heart rate	**Directly:** Cocaine, adrenergic β-agonists, sympathomimetics, abrupt discontinuation of β-blockers **Indirectly:** Potent vasodilators (nifedipine, minoxidil, hydralazine)
Increased myocardial contractility	**Directly:** Cocaine, adrenergic β-agonists, sympathomimetics, abrupt discontinuation of β-blockers **Indirectly:** Potent vasodilators (nifedipine, minoxidil, hydralazine, etc.)
Increased left-ventricular systolic wall tension (increased preload or increased afterload)	**Increased Preload:** NSAIDs

	Increased Afterload: Drugs that increase blood pressure (cocaine, phenylephrine, amphetamines, etc.)
Decreased myocardial oxygen supply (temporary, nontotal occlusion)	
o Increased coronary vascular resistance (vasospasm, thrombosis)	Cocaine, phenylephrine, amphetamines, anti-migraine agents (ergot alkaloids, triptans)
o Decreased coronary diastolic perfusion pressure	Enalapril, nifedipine, minoxidil, hydralazine, nitroprusside, adenosine, dipyridamole
Decreased oxygen carrying capacity	
Drug-Induced Acute Coronary Syndrome	
Acute coronary syndrome associated with acute drug therapy	
Coronary artery thrombosis, superimposed on a damaged atherosclerotic plaque	Cocaine, oral contraceptives, estrogens, COX-2 inhibitors, NSAIDs
Coronary artery vasospasm (with or without a superimposed coronary artery thrombosis)	Cocaine, antimigraine agents (ergot alkaloids, triptans)
Acute coronary syndrome associated with chronic drug therapy (drugs that increase cardiovascular risk)	Cocaine, estrogens, COX-2 inhibitors, NSAIDs, anti-HIV agents/protease inhibitors, oral contraceptives, rosiglitazone

COX = cyclooxygenase, HIV = human immunodeficiency virus, NSAID = nonsteroidal anti-inflammatory drug.

Myocardial oxygen supply is determined by coronary blood flow and the oxygen-carrying capacity of blood.[492] The most important of these determinants clinically is coronary blood flow. Normally, the arteriolar resistance vessels are the most important regulators of coronary blood flow, whereas large epicardial vessels are low-resistance vessels. Complex factors that determine coronary blood flow include duration of diastole and coronary vascular resistance. Coronary vascular resistance is determined by metabolic control, autoregulation, extravascular compressive forces, and humoral and neural factors. Drug therapy may reduce myocardial oxygen supply by influencing any of these determinants. Agents that cause thrombosis or vasospasm of large coronary epicardial vessels may reduce myocardial oxygen supply. However, drugs that cause microvascular changes should also be considered. Unfortunately, these changes are more difficult to assess clinically. Finally, oxygen-carrying capacity can be affected by conditions such as anemia.

There are several examples of drugs that may precipitate ischemia by decreasing myocardial oxygen supply. Cocaine causes myocardial ischemia not only via increases in heart rate and blood pressure but also via coronary vasoconstriction, which is mediated by cocaine-induced blockade of norepinephrine reuptake, leading to increased plasma norepinephrine concentrations and enhanced α_1-adrenoceptor-mediated vasoconstriction.[319,323,327,329] Some data also suggest that cocaine increases plasma concentrations of endothelin-1, a powerful vasoconstrictor that contributes to coronary vasospasm.[323] Each of these mechanisms contributes to cocaine-induced coronary artery vasospasm. The ergot alkaloids and associated derivatives are widely known to cause coronary vasoconstriction, the mechanism of which is simply an extension of the drug's therapeutic effect, cerebral vasoconstriction. Triptans, which are also used for the treatment of migraines, are contraindicated in patients with coronary artery disease. Like ergot alkaloids, the purported mechanism of increased myocardial ischemia associated with triptans is coronary artery vasoconstriction or vasospasm or both; in the case of triptans, this is mediated by agonism of 5-hydroxytriptophan receptors.

Drugs may reduce myocardial oxygen supply through aggressive reduction of blood pressure via arterial vasodilation, leading to reductions in diastolic perfusion pressure and coronary blood flow. Patients with existing coronary atherosclerosis are particularly at risk for drug-induced myocardial ischemia via this mechanism. Any drug that reduces blood pressure, especially potent vasodilators, may cause myocardial ischemia or an acute coronary syndrome. An observational study suggested that the short-acting dihydropyridine calcium-channel blocker nifedipine may increase the risk of ischemic events and MI in patients with coronary artery disease, likely through this mechanism.[186,204] This study was highly controversial and led to debate for many years. Although the debate was contentious in many ways, there was general agreement that short-acting dihydropyridine calcium-channel blocking agents such as the immediate-release formulations of nifedipine or nicardipine should be avoided in patients with coronary artery disease.[187] Whether or not these restrictions should be applied to all calcium-channel blockers remains a topic of debate. Another drug believed to increase the risk of acute MI by reducing coronary perfusion pressure is enalapril. In a landmark clinical trial, the Cooperative North Scandinavian Enalapril Survival Study-II, early intravenous administration of enalaprilat followed by oral enalapril therapy was not associated with a reduction in the incidence of mortality.[493] One postulated mechanism for this lack of benefit was early drug-induced hypotension resulting in reduced coronary perfusion pressure. Reduction in coronary perfusion pressures during the acute phase of an MI may lead to larger areas of subendocardial tissue damage. An additional example of this phenomenon is the concomitant use of phosphodiesterase-5 inhibitors, such as sildenafil, with nitrates, the combination of which may cause marked hypotension leading to reduced myocardial oxygen supply and consequent myocardial ischemia or infarction.[494] The combined use of these drug classes is discouraged by the manufacturers, national organizations, and government regulators.

An alternative to exercise stress testing as a means to functionally evaluate the clinical and cardiovascular responses is pharmacologic stress testing. These tests provide some prognostic and diagnostic information about the underlying coronary artery disease. Two types of drugs are used: coronary artery vasodilators (adenosine and dipyridamole) and agents that increase cardiac work (dobutamine and arbutamine). Unlike agents that increase cardiac work, adenosine and dipyridamole do not cause ischemia by increasing myocardial oxygen demand. Rather, these coronary artery vasodilators may cause myocardial ischemia by preferentially dilating normal coronary arteries versus diseased vessels. This "steals" blood flow away from diseased segments (frequently referred to as coronary steal). These drugs are used in a controlled setting and frequently cause myocardial ischemia, but MI induced by these drugs is uncommon.

DRUG-INDUCED ACUTE CORONARY SYNDROMES

The mechanism by which a drug can induce an acute coronary syndrome may be thought of in two different, yet complementary, pathways, related to the temporal nature of the event. First, acute drug therapy may cause an acute coronary syndrome. Second, drugs may increase the risk of an acute coronary syndrome with continued, long-term exposure, as a result of the drug increasing the underlying degree of cardiovascular risk. Certain drugs may increase both the acute and chronic risk. The following discussion addresses each of these situations.

ACUTE CORONARY SYNDROME ASSOCIATED WITH SHORT-TERM DRUG THERAPY

Classically, the pathogenesis of an acute coronary syndrome is an occlusion of an epicardial coronary artery caused by a coronary artery thrombosis superimposed on a ruptured atherosclerotic plaque.[495] Less commonly, an acute coronary syndrome may occur despite an absence of clinically significant coronary atherosclerosis and is caused by coronary artery vasospasm with or without a superimposed coronary artery thrombosis.[495] Even though this mechanism is believed to be less common, in one study, 31 prescription, nonprescription, and illicit drugs and approximately 100 cases were associated with drug-induced acute coronary syndrome caused by coronary artery spasm in teenagers and young adults.[142] The acute induction of a drug-induced acute coronary syndrome may occur in association with either of the above-described situations. In either case, for drug-induced MI to occur, coronary blood flow must be occluded for a sufficient amount of time to result in necrosis of myocardial tissue. Thus, a drug-induced acute coronary syndrome could result from drug-induced coronary vasospasm (e.g., cocaine) or drug-induced coronary artery thrombosis (e.g., estrogens, cocaine, COX-2 inhibitors). For example, in theory, selective COX-2 inhibitors, which do not inhibit COX-1 and therefore do not decrease plasma concentrations of platelet-derived thromboxane, may exert different influences on the occurrence of cardiovascular events than other nonselective NSAIDs such as aspirin or naproxen. Inhibition of COX-2 is believed to suppress the endothelial production of prostacyclin, while leaving the production of thromboxane A2, mediated by COX-1, relatively unaffected. This may lead to vasoconstriction, platelet aggregation, thrombosis, and ultimately an acute coronary syndrome.[20,22]

ACUTE CORONARY SYNDROME ASSOCIATED WITH LONG-TERM DRUG THERAPY/INCREASED CARDIOVASCULAR RISK

Drugs may also increase the risk of development of coronary artery disease by accelerating the natural course of pathogenesis of atherosclerosis. The following have been identified as modifiable risk factors by the AHA: cigarette smoking, elevated plasma low-density lipoprotein cholesterol concentrations, reduced plasma high-density lipoprotein cholesterol concentrations, hypertension, obesity, and diabetes.[496,497] Thus, any drug that alters these risk factors in a negative way has the potential to increase the risk of a coronary event. Examples of drugs that have been shown to accelerate the development of coronary atherosclerosis include protease inhibitors (via induction of dyslipidemia) and cocaine. Postmortem studies of cocaine abusers have shown that cocaine accelerates the development of atherosclerosis by causing structural changes in the endothelial membrane, resulting in increased permeability to low-density lipoproteins. In addition, cocaine has been shown to enhance white-cell migration and increase the expression of adhesion molecules in the endothelium.[323] Other examples of drug-associated acceleration of coronary atherosclerosis include oral contraceptives, COX-2 inhibitors, and rosiglitazone. Finally, there is evidence that statins may increase the risk for development of type 2 diabetes, although there is no evidence that this translates into an increase in the risk of MI.[498,499]

DRUG DISCONTINUATION

Several drugs are known to cause myocardial ischemia or acute coronary syndromes when therapy is abruptly discontinued, in most cases in patients who have underlying coronary artery disease (Table 23-1). There are several mechanisms by which this may occur. For example, abrupt discontinuation of β-blockers may lead to increased myocardial oxygen demand secondary to β-adrenoceptor upregulation and hypersensitivity to catecholamine stimulation. Following the short-term treatment of an acute coronary syndrome, discontinuation of heparin and aspirin leads to an increase in adverse cardiovascular events.[14] These events seem to “cluster” early (～10 hours) after discontinuation and have been attributed to rethrombosis in coronary arteries. Maintenance of aspirin therapy has been proposed as a means of reducing the risk of this phenomenon. Additional data have suggested that discontinuation of clopidogrel therapy may result in an increased risk of death or recurrent acute coronary syndrome.[6] In that study, the incidence of death and recurrent MI was higher during the first 90 days following clopidogrel discontinuation in patients with acute coronary syndromes who were treated medically or with intervention. The theoretical mechanism of this increased risk is platelet activation and increased thrombotic risk immediately upon discontinuation of therapy.[500] This has led to considerable research regarding the appropriate duration of dual antiplatelet therapy.[6] Some suggest that the risk of MI upon discontinuation of antiplatelet therapy is only increased in the presence of elevated thrombotic risk. Decisions regarding discontinuation of dual antiplatelet therapy are challenging, particularly in those individuals who require surgery and those with elevated thrombotic risk.[500] Finally, there is some evidence, although conflicting, that abrupt discontinuation of statins may increase the risk of cardiovascular events.[16] Further research in this area is required.

In summary, there are numerous mechanisms by which drugs may cause myocardial ischemia or acute coronary syndromes. Cocaine is an example of a drug that may cause this disease by multiple mechanisms, including increased myocardial oxygen demand (increased heart rate, contractility, blood pressure, and development of left ventricular hypertrophy), decreased myocardial oxygen supply (platelet aggregation and thrombus formation, coronary artery vasoconstriction), and enhanced development of coronary artery disease (premature atherosclerosis).

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

DRUG-INDUCED MYOCARDIAL ISCHEMIA

The clinical presentation of a patient with drug-induced myocardial ischemia is similar to that of any patient with angina or ischemia associated with atherosclerotic coronary artery disease. The most apparent difference is that drug-induced myocardial ischemia may occur in individuals who do not have, or who are not at risk for, coronary artery disease. For example, it is unusual for a young individual to present with symptoms consistent with myocardial ischemia. Pharmacists and other healthcare professionals must be aware of drugs, both licit and illicit, that may precipitate angina or an acute coronary syndrome and evaluate the causality in appropriate patients.

Typical signs and symptoms associated with angina pectoris are summarized in **Table 23-3**. Briefly, angina typically presents as substernal, retrosternal, or transsternal discomfort that radiates, usually, to the neck and left arm. The discomfort is usually characterized by a dull sensation, rather than a sharp or stabbing pain, and patients may describe it as a strangling or constricting sensation. Patients often use the following words to describe the discomfort: pressure, heaviness, fullness, squeezing, burning, aching, gas, vise-like, or anxiety. Anginal discomfort usually has a gradual onset and lasts only a few minutes if the precipitating factor is removed. In addition, relief is usually afforded by rest, sublingual nitroglycerin, or both. Longer durations of angina may imply severe myocardial ischemia, coronary vasospasm, unstable angina, or impending or ongoing MI.

Table 23-3 Clinical Presentation and Signs and Symptoms of Chest Pain Associated with Myocardial Ischemia

Quality

- Sensation of pressure or heavy weight on the chest
- Burning sensation in chest
- Chest tightness
- Shortness of breath with feeling of constriction about the larynx or upper trachea
- Visceral pain quality (deep, heavy, squeezing, aching)
- Gradual increase in intensity followed by gradual fading away

Location

- Over the sternum or very near the sternum
- Anywhere between epigastrum and pharynx
- Occasionally limited to left shoulder and left arm; rarely limited to right arm
- Limited to lower jaw
- Lower cervical or upper thoracic spine
- Left interscapular or suprascapular area

Precipitating factors

- Relationship to exercise
- Effort that involves use of arms above the head
- Weather factors (cold, warm and humid); walking against wind
- Large meal
- Emotional factors involved with exercise, fright, and/or anger
- Coitus
- Drugs

Nitroglycerin relief

- Relief of pain

Radiation

- Left arm and shoulder
- Jaw
- Right arm (occasionally)

Duration

- 0.5–30 minutes

DRUG-INDUCED ACUTE CORONARY SYNDROME

In most situations, the clinical presentation of a patient with drug-induced acute coronary syndrome is similar to that of any patient with nondrug-induced acute coronary syndrome. However, there are several exceptions to this generalization. Like myocardial ischemia, acute coronary syndromes are relatively unusual in young populations (<50 years of age). Approximately 25% of all acute MIs in individuals 18–45 years of age have been associated with frequent cocaine use.[329] The typical patient who presents with cocaine-induced acute coronary syndromes is a relatively young man who smokes cigarettes but does not have any other obvious cardiovascular risk factors. Thus, in younger patients without any obvious risk for acute coronary syndromes, the use of cocaine or other drugs that are known to be associated with drug-induced acute coronary syndromes should be considered. However, clinicians must contemplate the possibility of cocaine use in any patient who presents with an acute coronary syndrome. Because cocaine accelerates cardiovascular risk, it is certainly possible that its use is associated with acute coronary syndromes in older patients. Current recommendations suggest that urine screening for cocaine metabolites should be employed only in patients who are unable to communicate or when other sources of a reliable patient history are unavailable.[324]

As with cocaine, acute coronary syndromes associated with oral contraceptives usually occur in younger patients. The typical woman who presents with an acute coronary syndrome secondary to oral contraceptive therapy is usually over the age of 35 years and smokes cigarettes. The risk increases with age and appears to be higher in those with other cardiovascular risk factors, such as diabetes, hypertension, and dyslipidemia.[286]

Acute coronary syndromes classically present as prolonged chest discomfort described as oppressive pain, choking, squeezing, or burning that may radiate to the neck, throat, jaw, shoulders, or both arms. The discomfort associated with an acute coronary syndrome is generally similar in quality and location to anginal pain, except that the duration is longer (>30 minutes), it occurs at rest, and is not relieved by sublingual nitroglycerin or rest. Patients may present with other symptoms, such as nausea, vomiting, diaphoresis, shortness of breath, weakness, lightheadedness, or a sense of impending doom. Not all patients present with classic symptoms; some present with atypical signs or symptoms, are asymptomatic, or are unable to provide a history. The physical examination is not necessarily helpful in establishing the diagnosis of an acute coronary syndrome. However, the findings are important as a guide to immediate management and as a baseline for future comparison. Signs or symptoms of left or right ventricular dysfunction may be detected. Patients may present with bradycardia or tachycardia, low-grade fever, elevated respiratory rate, and leukocytosis. Most of these findings are nonspecific and do not confirm the diagnosis of an acute coronary syndrome.[425] The presentation of a drug-induced acute coronary syndrome is likely similar to that of other causes of acute coronary syndromes, although data are not available, except for that associated with cocaine. Patients with cocaine-induced acute coronary syndromes experience pressure-like chest discomfort, anxiety, palpitations, dizziness, and nausea. Dyspnea and diaphoresis occur in 60% and 40% of patients, respectively. However, it has been suggested that fewer than 50% of patients actually experience chest pain with cocaine-associated acute coronary syndromes, making the diagnosis more difficult.[324]

The classification and diagnosis of an acute coronary syndrome is based on three important features: chest pain, electrocardiographic changes, and serum biomarker (troponin) concentrations.[1,2,501] The diagnostic features of an acute MI are provided in **Table 23-4**. The classification and diagnosis of drug-induced acute coronary syndromes is generally performed in the same manner as with those that are nondrug-induced. Interested readers are directed to these guidelines for more in-depth discussion of the classification and diagnosis of an acute coronary syndrome.[1,2,501] These diagnostic features are likely to help differentiate drug-induced myocardial ischemia from drug-induced acute coronary syndromes. Conditions to consider in the differential diagnosis of drug-induced acute coronary syndromes are presented in **Table 23-5**.

RISK FACTORS

Specific risk factors for drug-induced myocardial ischemia or acute coronary syndromes are likely to be similar to those for nondrug-induced myocardial ischemia or acute coronary syndromes (**Table 23-6**). Although it may be difficult to predict which specific risk factors are necessary for increasing the risk of this disease associated with many of the causative agents, certain risk factors are well known to increase the risk of myocardial ischemia or acute coronary syndromes associated with cocaine, oral contraceptives, and estrogen-replacement therapy. Most patients with cocaine-related chest pain or acute coronary syndromes are younger than 50 years of age, nonwhite, male tobacco smokers with no history of coronary atherosclerosis. In fact, nearly 50% of patients with cocaine-related chest pain or MI do not have evidence of coronary atherosclerosis.[323,502] Tobacco smoking also increases the risk of a coronary event while taking oral contraceptives or hormone-replacement therapy.[473] This increase in the risk of a coronary event associated with smoking is consistent with the increased risk associated with smoking in patients with coronary artery disease or in those at high risk for a coronary event.

MORBIDITY AND MORTALITY

Patients with a history of coronary artery disease and ischemic heart disease who experience drug-induced chest pain and angina often attribute symptoms to those associated with their underlying disease process and may not seek additional medical care. However, depending on the severity of the drug-induced myocardial ischemia, these individuals may suffer recurrent disease exacerbations requiring additional care or alterations in drug regimens. It is likely that this situation occurs very commonly, but the cause is attributed to disease-induced ischemia rather than to drug-induced myocardial ischemia.

Table 23-4 Definition of Myocardial Infarction Based on the ESC/ACCF/AHA/WHF[501] Guidelines

Third Universal Definition of Myocardial Infarction

The term *myocardial infarction* should be used when there is evidence of myocardial necrosis in a clinical setting consistent with myocardial ischemia.

Under these conditions any one of the following criteria meets the diagnosis for myocardial infarction:

1. Detection of rise and/or fall of cardiac biomarkers [cTn] with at least one value above the 99th percentile of the URL together with at least one of the following:
    - Symptoms of ischemia
    - New/presumed new significant ST-T wave changes or new LBBB on the ECG
    - Development of pathological Q waves on the ECG
    - Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
    - Identification of an intracoronary thrombus
2. Cardiac death with symptoms suggestive of myocardial ischaemia and presumed new ischaemic ECG changes or new LBBB, but death occurred before cardiac biomarkers were obtained, or before cardiac biomarker values would be increased.
3. PCI-related MI is arbitrarily defined by elevation of cTn values (>5 × 99th percentile URL) in patients with normal baseline values or a rise of cTn values >20% if the baseline values are elevated and are stable or falling. In addition, either (a) symptoms suggestive of myocardial ischemia or (b) new ischemic ECG changes or (c) angiographic findings consistent with a procedural complication or (d) imaging demonstration of new loss of viable myocardium or new regional wall motion abnormality are required.
4. Stent thrombosis associated with MI when detected by coronary angiography or autopsy in the setting of myocardial ischaemia and with a rise and/or fall of cardiac biomarker values with at least one value above the 99th percentile URL.
5. Coronary artery bypass grafting-related MI is arbitrarily defined by elevation of cardiac biomarker values (>10 × 99th percentile URL) in patients with normal baseline cTn values (≤99th percentile URL). In addition, either (a) new pathological Q waves or new LBBB, or (b) angiographic documented new graft or new native coronary artery occlusion, or (c) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.

ACCF = American College of Cardiology Foundation, AHA = American Heart Association, cTn = cardiac troponin, ECG = electrocardiogram, ESC = European Society of Cardiology, LBBB = left bundle branch block, MI = myocardial infarction, PCI = percutaneous coronary intervention, URL = upper reference limit, WHF = World Heart Foundation.

Table 23-5 Conditions to Consider in the Differential Diagnosis of Drug-Induced Myocardial Ischemia and/or Acute Coronary

Syndrome

All drugs

- Nondrug-induced acute coronary syndrome and myocardial ischemia

Cocaine-induced acute coronary syndrome/myocardial ischemia

- Aortic dissection
- Pulmonary hypertension
- Acute pulmonary syndrome (“crack lung”)

Table 23-6 Risk Factors for Drug-Induced Myocardial Ischemia and/or Acute Coronary Syndrome

All drug-induced acute coronary syndrome/myocardial ischemia

- Pre-existing coronary artery disease

Cocaine-induced acute coronary syndrome/myocardial ischemia

- Smoking/tobacco use
- Ethanol use

Oral contraceptive-induced acute coronary syndrome

- Age >35 years
- High-dose estrogen
- Smoking/tobacco use
- Hypertension
- Diabetes
- Dyslipidemia

On the other hand, most patients in whom persistent chest pain develops with no history of coronary artery disease and those in whom a drug-induced acute coronary syndrome occurs seek medical attention, whether or not they have underlying coronary artery disease. Many of these patients require hospitalization and urgent treatment. Drug-induced acute coronary syndromes, like those that are nondrug-induced, may increase the risk of sudden death or death related to associated complications, including the development of left ventricular dysfunction, ventricular arrhythmias, or both.

There are considerable data describing the mortality associated with nondrug-induced acute coronary syndromes, and the statistics are alarming. Annual mortality rates for patients who experience a coronary event or MI are 37% and 16%, respectively.[429] Unfortunately, data regarding mortality associated with drug-induced chest pain and acute coronary syndromes are sparse, with the exception of those related to cocaine-induced coronary syndromes. The risk of mortality and recurrent MI associated with cocaine-induced chest pain is low (1-year risk approximately 2% and 1%, respectively).[503] With continued cocaine use, the risk of recurrent chest pain is very high. In patients who suffer a cocaine-induced MI, the risk of complications is substantially higher. In a study of patients with cocaine-induced MI, the risk of cardiac complications, most commonly heart failure and arrhythmias, was 38%.[321] The majority of complications occurred within the first 12 hours of hospitalization. Interestingly, no patients died during the hospitalization period. In another series, the risk of death associated with continued cocaine use was approximately 5%.[504]

PREVENTION

Approaches to help prevent drug-induced myocardial ischemia or acute coronary syndromes are listed in **Table 23-7**. Because patients with underlying coronary artery disease and those at high risk for the development of coronary artery disease are also likely to be at higher risk for the development of drug-induced myocardial ischemia or infarction, it is prudent to avoid drugs that may cause myocardial ischemia or infarction (Table 23-1) in this population unless treatment is absolutely necessary. If a potentially causative agent must be used, extra caution and monitoring should be used with these agents in patients at high risk for a coronary event (i.e., those with multiple risk factors, such as smoking, dyslipidemia, hypertension, diabetes mellitus, or others). In addition, the use of illicit drugs known to cause myocardial ischemia or infarction should be discouraged both in individuals and as a public health strategy. In patients with a history of coronary artery disease, particular attention to increased frequency of angina symptoms and/or use of sublingual nitroglycerin is warranted. More aggressive monitoring of chronic antianginal medications may be necessary.

Table 23-7 Approaches to Help Prevent Drug-Induced Myocardial Ischemia/Infarction

- Instruct patients who have a history of coronary artery disease to avoid, if possible, drugs that may cause myocardial ischemia or infarction.
- For patients who have underlying coronary artery disease and a previous history of anginal symptoms, self-care of angina symptoms should be the same as if the pain was associated with exertion or some other precipitant of an ischemic event.
- Individuals who do not have a history of coronary artery disease, acute coronary syndrome, or myocardial ischemia should be made aware that specific drugs that they are taking may, in unusual circumstances, precipitate a coronary event, and patients should be counseled regarding the symptoms that could result.
- Women >35 years of age should be assessed for cardiovascular risk (hypertension, smoking, diabetes, nephropathy and other vascular diseases) prior to initiation of oral contraceptives.
- Avoidance of drug toxicities through public health initiatives that warn about the dangers of illicit drug use.

There are no strong recommendations for considering drugs to be absolutely contraindicated in patients with known coronary artery disease for the avoidance of drug-induced myocardial ischemia and MI, with a few exceptions. The use of phosphodiesterase-5 inhibitors in patients receiving long-term nitrate therapy for exertional angina (i.e., patients with chronic coronary artery disease and angina) has been strongly discouraged by the AHA.[401] This strong statement is necessary because of the increased risk of coronary events and death when sildenafil is used in combination with short- or long-term nitrate therapy. Ergot alkaloids should also be avoided in patients with underlying coronary artery disease. In response to the clinical data suggesting an increase in cardiovascular events, NSAIDs have come under intense scrutiny. The next section discusses the use of NSAIDs in patients with cardiovascular disease.

In patients without a history of coronary artery disease, strategies for avoidance of drug-induced myocardial ischemia or infarction may be less clear. The approach in these patients should be increased awareness of drugs that have been associated with drug-induced myocardial ischemia or infarction. Unfortunately, no routine monitoring or prevention strategies can prevent drug-induced myocardial ischemia or infarction in all individuals. Recommendations for avoidance of use in specific conditions are available for only a few drugs. Regarding use of oral contraceptives, the Centers for Disease Control and Prevention (CDC)uses the following four classifications as a means for determining the risk–benefit ratio: **1** = A condition for which there is no restriction for the use of the contraceptive method; **2** = A condition for which the advantages of using the method generally outweigh the theoretical or proven risks; **3** = a condition for which the theoretical or proven risks usually outweigh the advantages of using the method; or **4** = a condition that represents an unacceptable health risk if the contraceptive method is used.[505] With respect to cardiovascular disease, the CDC indicates a rating of 3 or 4 for the following conditions: hypertension, multiple risk factors for atherosclerotic cardiovascular disease, vascular disease, current and history of ischemic heart disease and smoker with age >35 years. Dyslipidemia is rated as a 2 or 3 depending on the patient situation.[505]

MANAGEMENT

With the exception of the management of cocaine-induced chest pain and MI, there are very few specific data regarding the appropriate therapy for patients with drug-induced myocardial ischemia or acute coronary syndromes. Because the risk of the development of either disease in an otherwise normal population is very low, the consensus guidelines for the treatment of stable angina, unstable angina, or acute MI provide limited guidance about drug-induced diseases. More recent focused updates and scientific statements[1,2,324] have addressed cocaine-induced disease. However, limited information is available regarding other drugs known to cause myocardial ischemia or acute coronary syndromes.

With that introduction, it is most appropriate to consider treatment of three general groups: (1) patients with a history of chronic coronary artery disease who experience drug-induced ischemia; (2) patients with no history of coronary artery disease who experience drug-induced ischemia; and (3) patients with drug-induced acute coronary syndromes. In all three cases, it should be obvious that illicit drugs that are the cause of any of these drug-induced or drug-exacerbated diseases should be discontinued immediately and permanently.

DRUG-INDUCED MYOCARDIAL ISCHEMIA IN PATIENTS WITH CORONARY ARTERY DISEASE

Standard therapy for nondrug-induced myocardial ischemia secondary to coronary artery disease typically includes short-term management, long-term (prophylactic) therapy, and risk-factor modification.[506] Acute therapy typically involves the administration of sublingual nitrates when an anginal attack occurs or just before exertion in an effort to prevent or treat myocardial ischemia. In addition, most patients also require long-term prophylactic therapy with a β-blocker, calcium-channel blocker, a long-acting nitrate, or all three. The treatment of drug-induced myocardial ischemia is no different from that of classic nondrug-induced ischemia. Unless patients have been warned that a particular drug they are taking has the propensity to increase the risk of myocardial ischemia and subsequent angina, most patients will not associate an increase in the incidence of chest pain with specific drug therapy. Patients should be made aware that specific drugs they are taking might cause angina and potentially exacerbate their disease. When possible, the most effective treatment is to discontinue therapy with the offending agent. In some cases, this is not possible, and maximization of the patient’s medical therapy for the underlying myocardial ischemia is necessary.

DRUG-INDUCED MYOCARDIAL ISCHEMIA IN PATIENTS WITH NO HISTORY OF CORONARY ARTERY DISEASE

In most cases, the most effective and logical therapy is to treat the anginal episode with standard therapy as necessary and immediately discontinue therapy with the offending agent. Inasmuch as there is no apparent underlying disease (i.e., no atherosclerotic coronary artery disease), discontinuation of the offending drug removes the sole cause of the symptoms.[506] In certain situations, discontinuation of a culprit agent is impractical or even life threatening. For example, withholding therapy with a cancer chemotherapy agent may not be possible, because it may be the only effective treatment. In these cases, although no specific data are available to support this on all occasions, use of short-term or prophylactic therapies, such as sublingual nitrates, may be necessary to minimize the ischemia. In most other cases, however, discontinuation of the offending agent is the most effective treatment approach. Finally, as discussed in the section above, it is prudent to treat these individuals with therapies that reduce the risk factors.

DRUG-INDUCED ACUTE CORONARY SYNDROMES

The therapies for acute coronary syndromes are outlined in consensus guidelines and reviews and are summarized in **Table 23-8**.[1,2,324] The consensus guidelines outlined in the table illustrate standard treatment of acute coronary syndromes (ST-segment elevation [STSE] acute coronary syndromes and non-ST-segment elevation [NSTSE] acute coronary syndromes) and management of cocaine-induced acute coronary syndromes from two distinct guidelines. Management of methamphetamine-induced acute coronary syndromes is also described as analogous to treatment of cocaine-induced acute coronary syndromes. The only drug-induced acute coronary syndromes for which therapeutic guidance exists are those caused by cocaine and methamphetamine; a specific section is devoted to treatment of these.

The management of conventional (nondrug-induced) acute coronary syndromes typically includes antiplatelet agents, unfractionated heparin or low-molecular-weight heparin, nitrates, β-blockers, anxiolytic drugs, and analgesics. In patients with STSE acute coronary syndromes, the addition of revascularization therapy with percutaneous coronary intervention (PCI) or thrombolytic therapy is generally indicated, and glycoprotein IIb/IIIa receptor antagonists are used in selected patients. In patients with NSTSE acute coronary syndromes, thrombolytic agents are not indicated, but PCI and glycoprotein IIb/IIIa receptor antagonists may be used. In general, therapy for a drug-induced acute coronary syndrome is the same as that for a nondrug-induced acute coronary syndrome. The therapies are similar primarily because there are few data to suggest that they should be different. Following in-hospital care, patients with evidence of drug-induced MI or atherosclerosis should be treated in a manner similar to that of patients with a nondrug-induced acute coronary syndrome. Aggressive cardiovascular risk-factor reduction with smoking cessation therapy and control of hypertension, diabetes, and dyslipidemia is necessary. Treatment with traditional secondary prevention therapies, including aspirin, clopidogrel, β-blockers, statins, and angiotensin-converting enzyme inhibitors should also be administered in these patients.

TREATMENT OF COCAINE-INDUCED ACUTE CORONARY SYNDROMES

As illustrated in Table 23-8, treatment guidelines for cocaine-induced acute coronary syndromes have been published. In addition, new sections regarding cocaine have been added to consensus guidelines for the management of acute coronary syndromes.[1,2,324] Mechanisms of cocaine-induced acute coronary syndrome are multifactorial (increased myocardial oxygen demand, decreased myocardial oxygen supply due to vasoconstriction, and thrombus formation), but, unlike nondrug-induced acute coronary syndromes, a major component of cocaine's effect is secondary to coronary vasoconstriction (in contrast to that of a classic acute coronary syndrome). Therefore, treatment approaches target the vasoconstrictive component as well as the classic therapeutic targets. In addition, cocaine toxicity affects other organ systems, particularly the central nervous system, increasing the risk of seizures, hyperthermia, and subarachnoid hemorrhage. These factors must be considered when treating cocaine-induced acute coronary syndromes. The AHA's recommendations for treatment of cocaine-induced chest pain are provided in Table 23-8 and are based on risk profile. All patients should be evaluated in a chest pain unit and receive aspirin and benzodiazepines initially. If pain is not responsive, nitroglycerin, nitroprusside (for persistent hypertension not controlled with nitroglycerin) or phentolamine (alternative) are recommended. Please note that the two guidelines differ slightly in their approach.

Table 23-8 Therapy of Acute Coronary Syndromes

STEMI ACCF/AHA 2013 Guidelines[2]	NSTEMI/UA-ACCF/AHA 2014 Guidelines[1]		Cocaine-Associated Chest Pain and MI-AHA Scientific Statement[324]
	Overall Guidelines	Cocaine–Methamphetamine-Specific Guidelines	
Oxygen	Oxygen		Oxygen
Oral antiplatelet agents Aspirin $P2Y_{12}$ inhibitors	Oral antiplatelet agents Aspirin $P2Y_{12}$ inhibitors		Oral antiplatelet agents Aspirin $P2Y_{12}$ inhibitors
Benzodiazepine anxiolytics	Benzodiazepine anxiolytics	Benzodiazepines alone or in combination with nitroglycerin are reasonable for management of hypertension and tachycardia with signs of acute cocaine or methamphetamine intoxication	Benzodiazepine anxiolytics
Analgesics (morphine)	Analgesics (morphine)		Not discussed
Intravenous nitroglycerin	Intravenous nitroglycerin		Intravenous nitroglycerin (nitroprusside or phentolamine may be considered for persistent hypertension)
β-blockers	β-blockers	β-blockers should not be administered to patients with a recent history of cocaine or methamphetamine use who demonstrate signs of acute intoxication due to the risk of potentiating coronary spasm	β-blocker use should be avoided in the acute phase Labetalol does not offer any advantage; carvedilol has not been studied
Reperfusion Thrombolytics Primary PCI	Reperfusion Primary PCI	Not discussed	If ST-segment elevation present, PCI is preferred over thrombolytic therapy If NSTSE, evaluate with cardiac catheterization
Unfractionated heparin, enoxaparin, fondaparinux, bivalirudin	Unfractionated heparin, enoxaparin, fondaparinux, bivalirudin		Unfractionated heparin, enoxaparin, direct thrombin inhibitors
IV GP IIb/IIIa receptor antagonists	IV GP IIb/IIIa receptor antagonists		IV GP IIb/IIIa receptor antagonists
CCBs only when patients are unresponsive to NTG and β-blockers	CCBs only when patients are unresponsive to NTG and β-blockers		CCBs may be considered for patients who do not respond to benzodiazepines and nitroglycerin

ACCF = American College of Cardiology Foundation, AHA = American Heart Association, CCB = calcium-channel blocker, GP = glycoprotein, MI = myocardial infarction, NSTSE = non-ST-segment elevation, NSTEMI = non-ST-segment elevation myocardial infarction, NTG = nitroglycerin, PCI = percutaneous coronary intervention, STEMI = ST segment elevation myocardial infarction, WHO = World Health Organization, UA = unstable angina.

Considerable controversy exists regarding whether β-blockers, thrombolytic therapy, and calcium-channel blockers should be used for the management of cocaine-induced acute coronary syndromes. In theory, β-blockers have the potential to exacerbate coronary artery and systemic vasoconstriction. As described above, cocaine inhibits peripheral norepinephrine reuptake, leading to increased plasma norepinephrine concentrations and enhanced α_1-adrenoceptor-mediated vasoconstriction. When administered to patients who have ingested cocaine, β-blockers, especially nonselective agents, may further enhance coronary vasoconstriction through enhancement of unopposed α_1-adrenoceptor agonism, potentially further increasing blood pressure and heart rate and possibly increasing the risk of seizures and mortality.[319] Available data suggest that labetalol (a β-adrenergic and α_1-receptor inhibitor) may convey benefit in patients with cocaine-induced acute coronary syndromes, but labetalol administration has also been associated with increased seizure activity and mortality in animal models and little effect on coronary vasoconstriction in humans. Carvedilol, which is also a β-adrenergic and α_1-receptor inhibitor, may theoretically benefit patients with cocaine-induced acute coronary syndromes as well, although data supporting carvedilol use in this situation are not available. Several treatment guidelines[1,2,324] and expert reviews suggest that β-blockers of any kind should not be administered during the acute phase of an acute coronary syndrome. However, these recommendations have been questioned. Results of a retrospective study indicated that β-blockers are associated with a substantially lower risk of cocaine-induced MI.[507] The authors of this study suggested that warnings against β-blocker use may apply only to patients with acute cocaine intoxication. The AHA guidelines published in 2014 share these recommendations, whereas the cocaine-specific guidelines published in 2008 recommended against acute β-blocker administration. Further research since the publication of the 2008 guidelines suggests no difference in outcomes between the β-blocker cohort and patients not receiving a β-blocker.[508] However, it is difficult to determine if the patients in that study were acutely intoxicated. Both guidelines specifically recommend against the use of β-blockers in patients acutely intoxicated with cocaine.

Thrombolytic administration to individuals with cocaine-induced acute coronary syndrome is also very controversial. There have been several reports of intracranial hemorrhage or death secondary to thrombolytic use in this population.[317,509,510] Therefore, patients should receive benzodiazepines, aspirin, and nitrates followed by calcium-channel blockers or phentolamine.[317] Therapy with thrombolytics should be reserved for patients who are clearly having an ST-segment elevation MI who cannot undergo revascularization with PCI. These issues related to cocaine-induced acute coronary syndromes suggest that the standard treatment of drug-induced acute coronary syndromes is less than clear and is sometimes dependent on the specific drug causing the acute coronary syndrome.

The use of calcium-channel blockers for the treatment of cocaine-induced chest pain and acute coronary syndromes is also controversial. In theory, calcium-channel blockers should reverse the vasoconstriction frequently associated with cocaine ingestion. In cardiac catheterization studies, verapamil has been shown to reverse cocaine-associated vasospasm. However, results of animal studies regarding the effects of calcium-channel blockers on survival, seizure frequency, and arrhythmias associated with cocaine-induced ischemia have been variable.

Current recommendations suggest that the short-acting dihydropyridine calcium-channel blockers should never be administered in patients with cocaine-induced acute coronary syndromes. This recommendation is consistent with that of standard treatment of chronic and acute coronary syndromes. Verapamil or diltiazem should not be used in the presence of left ventricular systolic dysfunction. Therapy with calcium-channel blockers should be reserved for patients with cocaine-induced acute coronary syndromes who do not respond to therapy with nitroglycerin and benzodiazepines.[324]

Finally, after hospitalization, outpatient treatment of patients with evidence of cocaine-induced MI or atherosclerosis should be similar to that used for patients with a nondrug-induced acute coronary syndrome. Aggressive cardiovascular risk-factor reduction with smoking cessation therapy and control of blood pressure, diabetes, and plasma lipid concentrations is necessary. Traditional secondary prevention therapies including aspirin, clopidogrel, statins, and angiotensin-converting enzyme inhibitors should be administered in these patients. Therapy with β-blockers should be used if required based on risk and in consideration of the potential for continued cocaine use.

Finally, while there are limited options for drug treatment programs to reduce cocaine use, there are numerous options for psychosocial intervention. The combination of group and intensive individual counseling has promise for the treatment of cocaine dependence.

ALTERNATIVES TO THE USE OF NSAIDs

Current guidelines recommend against the routine use of nonselective NSAIDs and selective COX-2 NSAIDs in patients with acute coronary syndromes.[2,511] Although these recommendations are focused on the treatment of acute coronary syndromes, they should likely be applied to all patients with cardiovascular disease. During the acute period, narcotic analgesics such as morphine should be administered for pain management. Following discharge from the hospital and during the postinfarction period, the AHA recommends a stepped-care approach for managing musculoskeletal pain.[481] These recommendations strongly advise clinicians to closely evaluate symptoms and to use nonpharmacologic approaches initially. If these techniques are ineffective for pain control, first-line agents may include acetaminophen, aspirin, tramadol, short-term narcotic analgesics or nonacetylated salicylates. The next tier of therapy involves a progression from non-COX-2 selective NSAIDs (e.g., naproxen, ibuprofen) to NSAIDs with some selectivity (e.g., diclofenac, celecoxib) to COX-2 selective NSAIDs (e.g., rofecoxib, etoricoxib). The recommendations also suggest that once the second tier of agents is chosen, the lowest dose of NSAID should be used, and additional therapy should include aspirin 81 mg daily and a proton pump inhibitor.[481] These recommendations have been met with some disagreement, as they are based primarily on cardiovascular risk, rather than the need for pain management.

INFORMATION FOR PATIENTS

Information for patients regarding prevention of these drug-induced conditions is provided in Table 23-7. Patients who are taking drugs that may cause myocardial ischemia or acute coronary syndromes should be instructed that the specific drug may, in some cases, cause chest pain. For patients who have underlying coronary artery disease and a history of anginal symptoms, self-care of angina symptoms should be the same as if the pain was associated with exertion or some other precipitant of an ischemic event. Individuals who do not have a history of coronary artery disease, acute coronary syndrome, or myocardial ischemia should be made aware that specific drugs that they are taking may, in unusual circumstances, precipitate a coronary event, and patients should be counseled regarding the symptoms that could result. Patients should be instructed to consult their pharmacist or physician or go to an emergency department if chest pain, palpitations, lightheadedness, dizziness, or shortness of breath occur. Finally, and most unfortunately, many cases of drug-induced ischemia and infarction are associated with illicit-drug use (e.g., cocaine, amphetamines). The best method to avoid these toxicities is through public health initiatives that warn about the dangers of illicit-drug use. Finally, referral of these patients to drug rehabilitation programs is essential for appropriate treatment.
